John H. Houston

A TREATISE

ON THE

PRINCIPLES AND PRACTICE

OF

MEDICINE;

DESIGNED FOR THE USE OF

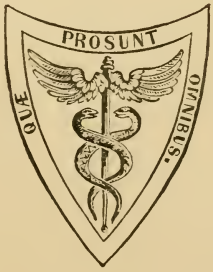
PRACTITIONERS AND STUDENTS OF MEDICINE.

BY

AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

FOURTH EDITION, CAREFULLY REVISED.



PHILADELPHIA:
HENRY C. LEA.
1873.

PREFACE TO THE FOURTH EDITION.

Since the publication of the Third Edition of this work, in October, 1868, the advances made in many departments of practical medicine have seemed to call for a thorough revision. In the performance of this duty the Author has sought to introduce the results of his continued clinical studies, together with the latest contributions to medical literature, both in Europe and this country, without changing the character of the volume as a condensed text-book and work of reference. This has required the rewriting of some portions, as well as numerous additions throughout, but more especially in the Section devoted to Diseases of the Nervous System, causing an increase in the text of about seventy pages.

To accomplish this has required no little labor, and in return the Author hopes for the satisfaction derivable from a continuance of the favor with which the work has hitherto been received by the profession.

New York, *April*, 1873.

PREFACE TO THE FIRST EDITION.

The object of this work is to present such a digest of the Principles and Practice of Medicine as will be serviceable alike to the pupil in the prosecution of his studies of disease, and to the physician engaged in the practical duties of his profession. The plan, at the outset, was to fulfil this object within the compass of one good-sized volume. In carrying out this plan, condensation has been necessary. As much conciseness as is consistent with clearness has been studied. Very little space will be found to be occupied with past opinions or doctrines which have become obsolete. Discussions relating to mooted pathological questions are rarely entered into. Illustrative cases have been introduced with reserve. As regards scope, the work embraces the subjects which generally enter into didactic teaching from the chair of the Principles and Practice of Medicine in the medical colleges of this country. Subjects belonging to other departments of instruction are, for the most part, omitted; hence, for information on matters relating to surgery, obstetrics, the diseases of women and children, cutaneous diseases, and the details of the Materia Medica, the reader is referred to other works. Finally, in writing the volume, the study has been to keep prominently in mind the practical applications of medical knowledge to diagnosis, prophylaxis, and therapeutical indications.

In submitting the work to the judgment of his fellow-teachers and practitioners, the author ventures to hope that it may be found to represent fairly the existing state of the science of Medicine with respect to the subjects of which it treats, and to reflect the views of those who exemplify, in their practice, the present stage of the progress of medical art.

New York, *January*, 1866.

CONTENTS.

INTRODUCTORY CHAPTER.

PAGE

Scope of the term Medicine—Use of the term in contradistinction to Surgery and Obstetrics—Subdivisions of the different departments of medicine, or specialties—The general object of this work—Meaning of the phrase Principles and Practice of Medicine—Definition of Pathology—Division into General and Special Pathology—Nomenclature of Diseases—Subdivisions of General Pathology, viz., Morbid anatomy, and morbid changes of the fluids of the body; Etiology; Symptomatology; Diagnosis; Prognosis; Prophylaxis; and Therapeutics—Relations of these subdivisions to Special, as well as General, Pathology—Definition of Disease—Definition of Health—Relationship of Pathology to Physiology—Progress of Pathological Knowledge 17

PART I.

PRINCIPLES OF MEDICINE, OR GENERAL PATHOLOGY.

CHAPTER I.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY.

Congenital Malformations—Three classes of Lesions, viz., Lesions of Quantity, of Consistence, and of Composition—Hypertrophy and Atrophy, Lesions of Quantity—Hypertrophy—True and False Hypertrophy—Atrophy—Atrophy with Increase and with Diminution of Volume—Lesions of Consistence—Induration—Softening—Inflammatory and Non-Inflammatory Softening 25

CHAPTER II.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(CONTINUED.)

Lesions of Composition—Exudations and Transudations—Fibrinous Exudation or Coagulable Lymph—Tubercle—Scrofula—Carcinoma or Cancer—Typhoid Deposit 31

CHAPTER III.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(Concluded.)

PAGE

Lesions of Composition, Continued—Transudation—Dropsies—Fluxes—Degenerations—Fatty Degeneration—Fatty Growth—Calcareous Degeneration—Lardaceous or Waxy Degeneration—New Formations or Morbid Growths—Pneumatoses—Animal and Vegetable Parasites 44

CHAPTER IV.

MORBID CONDITIONS OF THE BLOOD.

General Remarks—Classification of the Constituents of the Blood—Morbid Conditions relating to the Organized or Corpuscular Elements—Plethora—Anæmia—Apnœa—Leucocythemia 56

CHAPTER V.

MORBID CONDITIONS OF THE BLOOD—(Continued.)

Morbid Conditions relating to Fibrin, Hyperinosis, Hypinosis—Coagulated Fibrin within the cavities of the Heart—Coagulated Fibrin within the Bloodvessels—Embolism—Thrombosis—Morbid Conditions relating to Albumen—Dropsy as dependent on Diminution of Albumen—Morbid Conditions relating to Water in the blood—Hydræmia 69

CHAPTER VI.

MORBID CONDITIONS OF THE BLOOD—(Continued.)

Morbid Conditions relating to Fat—Morbid Conditions relating to Sugar—Diabetes Mellitus—Morbid Accumulation of Excrementitious Principles in the Blood—Uræmia—Excess of Uric Acid in Gout, Uricæmia—Retention of Excrementitious Principles contained in the Vapor of Expiration—Retention of Excrementitious Principles contained in the Perspiration—Reabsorption of Bile, or Cholæmia—Cholesteræmia—Morbid Conditions relating to the Saline Constituents of the Blood 81

CHAPTER VII.

MORBID CONDITIONS OF THE BLOOD—(Concluded.)

Morbid Conditions due to the presence of morbid products, intrinsic and extrinsic—Pyæmia—Putrid infection of the blood, or Septicæmia—Matter of contagion—Viruses—Infectious Miasms—Venoms—Poisons, palpable, and impalpable or miasms—Zymosis—Considerations which lead to the inference of the prior existence of a constitutional or general morbid condition, or indeterminate blood-changes, in various local affections 99

CHAPTER VIII

THE CAUSES OF DISEASE, OR ETIOLOGY.

PAGE

Etiology a branch of General and Special Pathology—Its Importance—Internal or Intrinsic and External or Extrinsic Causes—Ordinary, and Special or Specific Causes—Traumatic Causes—Spontaneous Diseases—Primary and Secondary Causes—Complications and Intercurrent Diseases—Predisposing and Exciting Causes—Congenital and Inherited Predispositions to Disease—Co-operating Causes—Diathesis—Cachexia or Dyscrasia—Endemic Diseases dependent on Emanations from the soil—Epidemic Diseases produced by Causes existing in the Atmosphere—The Causes of some Contagious Diseases exclusively derived from those affected with these Diseases, and other Diseases of this class produced, in some cases, by other Causes than Contagion or Infection—Fomites—Portability of the special Causes of Diseases not Contagious nor Infectious—The Causes of Contagious and Infectious Diseases probably Living Germs or Organisms 103

CHAPTER IX.

SYMPTOMATOLOGY.

Pathognomonic Symptoms—Diagnostic Symptoms—Subjective and Objective Symptoms—Signs—Clinical History of Diseases and the different Modes by which it is obtained—Stages of Disease—Precursory or Prodromic Events—Sequels—Diagnosis—Reasoning by way of Exclusion—Differential Diagnosis—Prognosis—Prognostics 111

CHAPTER X.

PROPHYLAXIS—GENERAL THERAPEUTICS.

Experience the Basis of Therapeutical Knowledge—Two Sources of Experience; Analysis of recorded Cases with reference to the Duration or Termination of Diseases and Observation of the Immediate effects of Therapeutical Measures—Rational Inference as a means of arriving at Principles of Therapeutics—Importance of Knowing the Intrinsic Tendencies of Diseases toward Recovery or otherwise—Active Measures to be employed only when clearly indicated—The Expectant Plan of Treatment—Conservative Medicine—Importance of Hygienic Measures of Treatment—Modes of Dying resolvable into Apnœa and Asthenia—Classification of Therapeutical Measures, according to the Objects to be accomplished, into Prophylactic, Abortive, Curative, Palliative, Hygienic, and Sustaining Measures—Consideration of the Elementary Forms of Disease deferred . 124

PART II.

PRACTICE OF MEDICINE, OR SPECIAL PATHOLOGY.

INTRODUCTION.

PAGE

Of the different aspects under which Individual Diseases are to be Considered, in treating of the Practice of Medicine, or Special Pathology—viz., Anatomical Characters, Clinical History, Pathological Character, Causation, Diagnosis, Prognosis, Prevention, and Treatment—Sense of the Term Individual as applied to a Disease, and the several Grounds of Individuality—Varieties of a Disease—Definition of the Terms Acute, Subacute, and Chronic—The Symptoms or Events incidental to Disease sometimes, for convenience, considered as Individual Diseases—Self-limited Duration of Certain Diseases—Nosology—Nosological Arrangement adopted in this Work 133

SECTION FIRST.

DISEASES AFFECTING THE RESPIRATORY SYSTEM.

CHAPTER I.

Division of the Diseases affecting the Respiratory System into Inflammatory and Non-inflammatory—Acute Pleuritis—Anatomical Characters—Clinical History—Pathological Character—The Natural History of Inflammation, and our Knowledge of its essential nature—Causation of Pleuritis—Diagnosis—Prognosis . 137

CHAPTER II.

Treatment of Acute Pleuritis—Measures indicated in the First Stage—General Considerations relating to Bloodletting in Acute Inflammations—The use of Opium in Acute Pleuritis and other Acute Inflammations—Measures indicated in the Second and the Third Stage of Acute Pleuritis 148

CHAPTER III.

VARIETIES OF PLEURITIS.

Chronic Pleuritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Prognosis—Treatment—Thoracentesis. Suppurative Pleuritis, or Empyæmia — Diagnosis—Prognosis—Treatment. Pleuritis with Pneumothorax — Anatomical Characters—Clinical History — Diagnosis — Prognosis—Treatment. Pneumothorax. Circumscribed Pleuritis. Hydrothorax. . . 156

CHAPTER IV.

PNEUMONITIS.

PAGE

Seat of the Inflammation. Varieties. Acute Lobular Pneumonitis—Anatomical Characters—Laws of the Disease—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis 174

CHAPTER V.

Treatment of Acute Lobular Pneumonitis. Pneumonitis in Young Children. Circumscribed Pneumonitis. Chronic Pneumonitis—Induration—Sclerosis and Cirrhosis of the Lung. Pigment, or brown induration. Anthracosis. Siderosis. Lobular Pneumonitis—Atelectasis and Collapse of Pulmonary Lobules. Pleurodynia and Intercostal Neuralgia 188

CHAPTER VI.

BRONCHITIS.

Acute Bronchitis affecting the Large Bronchial Tubes—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute Bronchitis. Acute Bronchitis in Young Children. Bronchitis affecting the small Bronchial Tubes. Epidemic Bronchitis. Bronchitis with Fibrinous Exudation. Circumscribed Bronchitis. Chronic Bronchitis . 206

CHAPTER VII.

Emphysema of the Lungs. Interlobular or Interstitial Emphysema. Subpleural Emphysema. Vesicular Emphysema or Dilatation of the Air-Cells—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Asthma—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Pertussis, Whooping Cough . 222

CHAPTER VIII.

Pulmonary Hemorrhage. Bronchorrhagia. Pneumorrhagia. Pulmonary Gangrene. Pulmonary Œdema. Carcinoma within the Chest. Hydatids . . 246

CHAPTER IX.

Affections of the Larynx and Trachea. Points relating to the Anatomy and Physiology of the Larynx which are involved in the consideration of Diseases in this situation. Acute Simple Laryngitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute Laryngitis. Chronic Laryngitis. Laryngitis with Exudation of Lymph—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Œdema of the Glottis. Spasm of the Glottis. Nervous Aphonia. Morbid Growths 260

CHAPTER X.

PULMONARY TUBERCULOSIS.

PAGE

Definition and Scope of the Term Pulmonary Tuberculosis—Anatomical Characters —Clinical History—Pathological Character—Causation 284

CHAPTER XI.

PULMONARY TUBERCULOSIS—(Concluded.)

Diagnosis—Prognosis—Treatment. Acute Pulmonary Tuberculosis . . . 299

SECTION SECOND.

DISEASES AFFECTING THE CIRCULATORY SYSTEM.

CHAPTER I.

Introductory Remarks. Pericarditis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Chronic Pericarditis. Pneumo-Pericarditis 315

CHAPTER II.

Endocarditis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Myocarditis 326

CHAPTER III.

VALVULAR LESIONS WITH ENLARGEMENT OF THE HEART.

Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment 333

CHAPTER IV.

Enlargement of the Heart without Valvular Lesions. Hypertrophy. Dilatation. Atrophy of the Heart. Fatty Degeneration and Softening of the Heart. Rupture of the Heart. Functional Disorder of the Heart. Enlargement of the Thyroid Body and Prominence of the Eyeballs associated with Functional Disorder of the Heart. Angina Pectoris. Thoracic Aneurism 347

SECTION THIRD.

DISEASES AFFECTING THE DIGESTIVE SYSTEM.

CHAPTER I.

PAGE

Introductory Remarks. Sporadic Dysentery—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Epidemic Dysentery. Chronic Dysentery. Inflammation of the Cæcum. Perforation. Fecal Abscess. Painful Tumor near the Cæcum 366

CHAPTER II.

Acute Enteritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Enteritis. Acute Gastritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Gastritis. Duodenitis. Pharyngitis. Parotiditis 383

CHAPTER III.

STRUCTURAL AFFECTIONS OF THE STOMACH.

Induration. Softening. Gastric Ulcer. Carcinoma of Stomach. Dilatation of Stomach. Degeneration of the Gastric Tubules 402

CHAPTER IV.

Structural Affections of the Intestinal Canal involving Obstruction—Invagination—Strangulated Hernia within the Abdomen—Rotation or twisting of Intestine—Compression and Stricture of Intestine. Obstruction from Impaction of Feces, Enterolithes, and Foreign Bodies. Functional Obstruction. 419

CHAPTER V.

Functional Affections of the Stomach and Intestines—Dyspepsia—Polyphagia, Malacia or Pica, Polydipsia, Dipsomania. Gastrorrhagia 431

CHAPTER VI.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINES—(Continued.)

Inanition. Gastralgia. Passage of Gall-Stones. Diarrhœa. Enterorrhagia . 450

CHAPTER VII.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINES—(CONTINUED.)

PAGE

Constipation. Intestinal Colic. Enteralgia. Lead Colic 469

CHAPTER VIII.

Sporadic Cholera—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Cholera Infantum. Epidemic Cholera—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Prevention—Treatment 483

CHAPTER IX.

INTESTINAL WORMS.

Ascaris Lumbricoides. Ascaris or Oxyuris Vermicularis. Tricocephalus Dispar. Anchylostoma Duodenale. Ascaris Alata. Tæniæ. Trichina Spiralis . . 512

CHAPTER X.

Acute General Peritonitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Partial Peritonitis. Chronic Peritonitis. Hydro-Peritoneum 526

CHAPTER XI.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN.

Acute Diffuse Hepatitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Circumscribed Suppurative Hepatitis. Suppurative Portal Phlebitis. Cirrhosis of the Liver . 546

CHAPTER XII.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN—(CONTINUED.)

Fatty Liver. Waxy or Lardaceous Liver. Cancer of the Liver. Tuberculosis of the Liver. Acute Atrophy of the Liver. Hydatid Tumors of the Liver. Pigmentary Deposit within the Liver. Hypertrophy of the Liver 562

CHAPTER XIII.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN—(CONCLUDED.)

Diseases Affecting the Biliary Passages. Jaundice, or Icterus. Functional Affections of the Liver. Affections of the Spleen. Affections of the Pancreas . . 579

SECTION FOURTH.

DISEASES AFFECTING THE NERVOUS SYSTEM.

CHAPTER I.

PAGE

Preliminary Remarks. Congestion of the Brain, Active and Passive. Cerebral Anæmia. Apoplexy. Cerebral Hemorrhage and other Anatomical Conditions. Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Insolation, or Sunstroke. Congestion and Anæmia of the Spinal Cord. Hemorrhage within the Spinal Canal 594

CHAPTER II.

Pachymeningitis and Hematoma of the Dura Mater—Acute Cerebral Meningitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Chronic Meningitis. Tuberculous Meningitis. Spinal Meningitis. Cerebro-Spinal Meningitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Hydrocephalus. Hydrorachis 625

CHAPTER III.

Cerebritis, and Abscess of the Brain. Structural Lesions within the Cranium. Induration or Sclerosis. Non-Inflammatory Softening of the Brain. Morbid Growths or Tumors within the Cranium. Psammona of the Brain. Hypertrophy and Atrophy of the Brain. Myelitis. Structural Lesions within the Spinal Canal 650

CHAPTER IV.

Paralysis, General Remarks on. Paralysis of the Third Cranial Nerve. Paralysis of the Fourth Cranial Nerve. Paralysis of the Fifth Cranial Nerve. Paralysis of the Sixth Cranial Nerve. Paralysis of the Seventh Cranial Nerve. Paralysis of the Eighth Cranial Nerve. Paralysis of the Ninth Cranial Nerve. Local Paralysis of other than Cranial Nerves. Paralysis of the Cervical Sympathetic Nerve. Paralysis from Lead 665

CHAPTER V.

Hemiplegia. Paraplegia 678

CHAPTER VI

General Spinal Paralysis. Treatment of Paralysis. Glosso-labial Paralysis. General Cerebral Paralysis. Progressive Locomotor Ataxia. Progressive Muscular Atrophy. Pseudo-hypertrophic, or myo-sclerotic paralysis. Scleroderma. Neuritis 698

Scorbutus, or Scurvy—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Prevention—Treatment. Purpura Hemorrhagica. Hæmatophilia 1050

INDEX 1061

THE

PRINCIPLES AND PRACTICE

OF

MEDICINE.

INTRODUCTORY CHAPTER.

Scope of the term Medicine—Use of the term in contradistinction to Surgery and Obstetrics—Subdivisions of the different departments of medicine, or specialties—The general object of this work—Meaning of the phrase Principles and Practice of Medicine—Definition of Pathology—Division into General and Special Pathology—Nomenclature of Diseases—Subdivisions of General Pathology, viz., Morbid anatomy, and morbid changes of the fluids of the body; Etiology; Symptomatology; Diagnosis; Prognosis; Prophylaxis; and Therapeutics—Relations of these subdivisions to Special, as well as General, Pathology—Definition of Disease—Definition of Health—Relationship of Pathology to Physiology—Progress of Pathological Knowledge.

MEDICINE, in the largest sense of the term, comprehends everything pertaining to the knowledge and cure of disease. In a more restricted sense, the term is used in contradistinction to Surgery and Obstetrics. The latter are properly departments of medicine in the comprehensive sense of the term; and, although they may be cultivated separately, they cannot be disconnected from principles which are common to them and to medicine in its restricted sense. The medical profession embraces all who devote themselves to the study and practice of medicine proper, surgery, and obstetrics, either separately or combined. The physician is a member of the profession who devotes his attention to the diseases which belong to the department of medicine proper, *i. e.*, medicine in the restricted sense of the term. The physician may, or may not, undertake the duties which belong to surgery and obstetrics. In this country most physicians are, of necessity, to a greater or less extent, also surgeons and obstetricians, in other words, general practitioners. It is only in cities and large towns that practitioners can devote themselves exclusively, or chiefly, to surgery and obstetrics as separate departments of medicine. The distinction of physician, surgeon, and obstetrician, in this country, is purely conventional. The only degree conferred by our universities and medical colleges is that of Doctor of Medicine, which authorizes the practice of either or all the departments, and the same is true of licenses to practise medicine.

The division of medicine into the three departments which have been named is natural, and has contributed to the knowledge acquired in each department. Subdivisions have also been found convenient and useful. The latter are commonly known as specialties, and they who devote themselves to particular subdivisions are called specialists. The more important of the subdivisions now recognized as specialties are affections of

the eye and ear, diseases of the skin, syphilitic affections, diseases peculiar to females, orthopedic surgery, disorders of the mind and nervous system, and diseases of the chest. Specialties result from an increase of knowledge rendering it difficult or impossible for one mind to compass all that has been ascertained in either of the three departments of medicine. Doubtless the number of specialties will be greater as our knowledge continues to increase. The special cultivation of the several subdivisions of medicine leads to a further development of knowledge relating to each subdivision, and, hence, conduces to the progress of medicine. But, as the great principles of medicine are common to medicine proper, surgery, and obstetrics, so with regard to the subdivisions, they cannot be completely isolated from the departments to which they respectively belong. A particular class of affections cannot be studied satisfactorily to the entire exclusion of others, and without reference to the general laws of disease. Directing the attention too exclusively to a specialty leads to the habit of attributing to it an undue relative prominence, and of regarding the affections belonging to it as of paramount importance when they may be secondary or merely incidental to others which, from being overlooked or not sufficiently appreciated, fail to receive appropriate treatment.

The object of this work is to present the outlines of Medicine proper, that is, of medicine in contradistinction to Surgery and Obstetrics. *The Principles and Practice of Medicine* is a title of this department considered as a province of medical teaching. This title is here adopted in preference to others, such as the Theory and Practice of Physic, General and Special Pathology, Pathology and Practical Medicine, or the Science and Practice of Medicine. The principles and practice of medicine comprehend everything pertaining directly to the knowledge and cure of those diseases which the physician is called upon to treat. The province of medical teaching thus designated properly enough embraces the prevention of disease, and it may include anything which concerns the conduct of the physician in the treatment of patients affected with disease.

The study of disease, as a province of scientific knowledge, is called *Pathology*. This province consists of two important divisions distinguished by the names *General* and *Special Pathology*. It is desirable to have a clear understanding of the terms which distinguish these two divisions of pathology. Diseases are presented in particular forms or species, constituting what are commonly known as individual diseases. The circumstances which give to the different diseases their individuality will be noticed hereafter. Now, the study of individual diseases constitutes special pathology. On the other hand, there are morbid conditions which are not peculiar to any individual disease, but are common to a greater or less number of diseases. The study of these conditions constitutes general pathology. Inflammation, for example, is a morbid condition which exists in a host of individual diseases. The study of inflammation, in so far as it is common to different diseases, belongs to general pathology, while the study of the numerous individual inflammatory diseases belongs to special pathology. To take another illustration: a morbid condition which enters into a number of individual diseases is called fever. In this sense of the term fever, it belongs to general pathology; but the study of the different forms of fever, or individual fevers, belongs to special pathology. The relation of general to special pathology is analogous to the relation of general to special anatomy, the former describing the several tissues which enter into the composition of the different organs of the body, and the latter describing the particular organs composed of the tissues. As the number of tissues is small in compari-

son with the number of organs. so the morbid conditions belonging to general pathology are few as compared with the great number of diseases belonging to special pathology.

The province of medical teaching entitled the Principles and Practice of Medicine is made up of general and special pathology. The subjects which belong to the principles of medicine are derived from general pathology. The principles of medicine and general pathology are, in fact, synonymous terms, each term having the same scope of application. And, in like manner, the subjects which belong to the practice of medicine are derived from special pathology. These two terms relate to the same division of pathological knowledge, the former term being somewhat more comprehensive in its scope than the latter. The principles of medicine, thus, on the one hand, and the practice of medicine, on the other hand, constitute divisions which coincide with the two divisions of pathology distinguished as general and special. Moreover, these divisions are in accordance with the distinctions expressed by the terms Science and Art. "Science is knowledge reduced to principles; art is knowledge reduced to practice." The principles of medicine constitute medical science; the practice of medicine is the exercise of medical art. The object of this work being to present the outlines of both the principles and the practice of medicine, or of both general and special pathology, or, again, of medical science and art, it will be divided into two parts corresponding to these divisions. The outlines of the principles of medicine, or general pathology, will form the *First Part* of the work, and the *Second Part* will be devoted to the practice of medicine, or special pathology. In adopting this arrangement, however, I shall not be bound by it so closely as to treat of the topics belonging to general pathology exclusively in the first part of the work. It will be more convenient to defer the consideration of some of these topics, and to treat of them incidentally in connection with individual diseases. Moreover, I shall treat of general pathology in its relation to medicine, passing over, or noticing very briefly, those topics which are chiefly important in a surgical point of view. Although the general principles of pathology are common to both medicine and surgery, certain topics have relations especially to either the one or the other of these departments. The terms *medical pathology* and *surgical pathology* are used in conformity with this distinction.

The subjects of General Pathology, namely, the morbid conditions common to a greater or less number of individual diseases, are to be considered under various points of view; hence, this division of pathology admits of several subdivisions. One point of view relates to nomenclature, or the naming of diseases. The great desideratum in nomenclature, as applied to diseases, is, that the name of each disease shall express the morbid condition involved, and its situation. The names which were formerly applied to different forms of disease were frequently fanciful, and many of these are still in use, owing to the difficulty and inconvenience of displacing them after they have become established in medical literature; and in not a few instances it is by no means easy, with our existing knowledge of the essential character of morbid conditions, to substitute more appropriate names. Some approach, however, has been made toward a nomenclature which shall measurably secure the advantages derived from this source in other branches of knowledge, more especially in chemistry. The existence of inflammation, which enters into so large a number of individual diseases, is expressed by the suffix *itis* (ιτης) added to the anatomical name of the part affected. Thus,

bronchitis, pneumonitis, pleuritis, peritonitis, etc. etc., are names denoting the inflammatory character of the diseases to which they refer, and the particular structure which is the seat of the inflammation. The suffix *œa* (ῥεω) denotes the existence of the morbid condition known as transudation, or flux, occurring in a situation where the transuded liquid escapes upon a mucous surface. Examples are enterorrhœa, bronchorrhœa, gastrorrhœa, cystorrhœa, terms which have not, as yet, come sufficiently into vogue. The suffix *rhagia* (ῥηγννμι) expresses a flow of blood, or hemorrhage from a mucous surface. Examples are metrorrhagia, gastrorrhagia (hæmatemesis), enterorrhagia (melæna), bronchorrhagia (hæmoptysis), in like manner terms which have not displaced others in common use. The suffix *algia* (ἀλγος) signifies a morbid condition characterized by pain without inflammation. Thus, neuralgia is a general term applied to this condition affecting any nerve or nerves; gastralgia, enteralgia, pleuralgia, etc., are terms severally expressing the neuralgic character of the affection and its seat. Words ending in *æmia* (ἀιμα) are applied to certain morbid conditions of the blood. Examples are anæmia (impoverishment of the blood), uræmia (morbid accumulations of urea in the blood), septicæmia (putrid infection of the blood), and pyæmia (purulent infection of the blood). Words ending in *uria* (ὀνρον) are applied to certain morbid conditions of the urine. Examples are albuminuria, hæmaturia, and oxaluria. The prefix *hydro* (ὑδωρ) denotes a dropsical affection of the part named; as hydrothorax, hydrocephalus, hydro-peritoneum, hydro-pericardium. And the prefix *pneumo* (πνευμα) denotes the presence of air in the part; as pneumothorax, pneumo-pericardium.

It is thus seen that, within late years, the effort to introduce names expressive of the character and seat of morbid conditions has, in a measure, succeeded. Further improvement in nomenclature will doubtless be made as our pathological knowledge increases.

An important subdivision of General Pathology relates to the appreciable morbid changes of the solids and fluids of the body. The study of all changes appreciable by the naked eye, or with the help of the microscope, constitutes a branch of pathology of great importance called morbid anatomy. Morbid anatomy is not confined to the study of the changes which occur in the tissues or solid parts; it embraces any changes which the eye can appreciate in the fluids of the body. The latter, not less than the former, are to be distinguished as anatomical, whereas those changes which are not visible either with the naked eye or by means of the microscope, but require for their detection processes of analysis or the employment of reagents, are usually considered as falling, not within the scope of morbid anatomy, but within the domain of animal chemistry. Prof. Charles Robin, however, considers the term anatomy to embrace investigation by means of analytical processes or reagents, as well as by means of dissection. Morbid changes not visible, or not yet ascertained with our present means of observation, are distinguished as *functional*, and are also said to be *dynamic*. Doubtless in all the so-called functional or dynamic deviations from health there are either molecular or cellular, that is, anatomical changes, at present inappreciable, or, at all events undiscovered, which may be hereafter ascertained by continued investigation with improved means of observation. Appreciable anatomical changes, which are either permanent or more or less persisting, are distinguished as *lesions*. The study of the minute anatomy of the tissues and fluids of the body with the microscope is called *Histology*, and the term *Morbid or Pathological Histology* is sometimes used to

designate that part of morbid anatomy relating to those abnormal changes which are objects of microscopical research.

Anatomical changes, or lesions, belong to general pathology in so far as they are common to a greater or less number of individual diseases. Their consideration, as involved in individual diseases, enters into special pathology or the practice of medicine. Such is the extent, as well as importance, of morbid anatomy, that it constitutes a distinct branch of medical knowledge. Treatises are specially devoted to it, and these are to be studied, in conjunction with the examination of morbid specimens, in order to become fully and practically acquainted with the various changes in structure, form, size, etc., which are incident to disease. It is a fact, however, not to be lost sight of, that lesions do not constitute, but are the results of, disease. In other words, they are always due to underlying morbid actions or processes which may not be directly appreciable or well understood, but in which really consists the local affection. This fact, although obvious, is apt to be overlooked. Lesions are, of course, serious or otherwise, according to their character, their situation, and the amount of structural change involved. The plan of this work embraces, in *Part First*, the outlines of morbid anatomy in so far as it belongs to medical pathology, inclusive of known changes in the most important fluid of the body—the blood; and, in *Part Second*, a concise account of the lesions characterizing different individual diseases.

Another subdivision of General Pathology relates to the causation of disease. The study of the causes of disease is called *Etiology*. As belonging to general pathology or the principles of medicine, this branch of medical knowledge will be considered in *Part First* of the work; and the causes involved in the production of each of the individual diseases will be embraced in the account of the latter in *Part Second*.

The great number and variety of phenomena or events to which disease gives rise constitute another subdivision of General Pathology. These phenomena or events are called symptoms, and their study constitutes a branch of medical knowledge called *Symptomatology or Semeiology*. Considerations relating to symptomatology, as belonging to general pathology, will claim attention in *Part First;* and the symptoms of individual diseases, respectively, forming, as they do, a highly important part of Special Pathology, or the practice of medicine, will be considered in *Part Second*.

Closely connected with symptomatology is another subdivision of General Pathology called *Diagnosis*. Diagnosis is the discrimination of diseases from each other. General considerations relating to this branch of medical knowledge will enter into *Part First*. In treating of individual diseases in *Part Second*, the means of discriminating them will be found to possess an importance second only to their treatment, and to be an essential prerequisite for the latter.

Another subdivision which will claim notice in both parts of this work is *Prognosis*, or the prediction of the termination of diseases.

The prevention of disease forms a branch of medical knowledge called *Prophylaxis*. This belongs alike to General and Special Pathology.

Lastly, the treatment of disease is called *Therapeutics*. General principles relating to the treatment of disease may be appropriately considered in connection with General Pathology. This portion of the subject is distinguished as *General Therapeutics*. I shall devote to it, together with prophylaxis, a chapter in *Part First*. It is hardly necessary to add that the treatment of individual diseases, distinguished as *Special Therapeutics*, is, in a practical view, the most important of the different aspects

under which they are to be considered, being, in fact, the great end of both the principles and the practice of medicine.

It is thus seen that the foregoing subdivisions of General Pathology, which will be taken up successively in the first part of this work, represent also the different points of view under which individual diseases are to be considered in the second part of the work; that is, individual diseases, as well as the morbid conditions common to a greater or less number of diseases, are to be considered with reference to the morbid changes either of solids or fluids which they may respectively involve, together with their causes, their symptoms, their discrimination or diagnosis, their prognosis, their prevention, and their treatment. Morbid anatomy, etiology, symptomatology, diagnosis, prognosis, prophylaxis, considered as branches of medical knowledge, belong to General Pathology, and to these may be added general therapeutics; and, on the other hand, Special Pathology, or the practice of medicine, considers the truths contained in these subdivisions of general pathology in their application to individual diseases.

Pathology has been defined the study of disease; but disease has not yet been defined. The definition of disease is confessedly difficult. It is easier to define it by negation, to say what it is not, than to give a positive definition, that is, a definition based either on the nature or essence of the thing defined, or on its distinctive attributes. Disease is an absence or deficiency of health; but this is only to transfer the difficulty, for the question at once arises, how is health to be defined? And to define health is not less difficult than to define disease. If all the tissues and organs of the body have their normal integrity and properties, if the fluids of the body are in no respect abnormal, if all the functions of the organism are completely and harmoniously performed, health undoubtedly exists. But this perfection of health is purely ideal; it never actually exists. An examination of the bodies of the healthiest persons would probably reveal lesions of some kind; certain deviations from the normal composition of the different fluids are not inconsistent with the evidences of health in other respects; functions of different parts may be disordered to a certain extent without sufficient disturbance to constitute disease. Gradations of health are implied in the qualifications of this term in common use. If the term health expressed a well-defined state, it would be a pleonasm to add to the term, as is often done, the adjectives good, excellent, etc.; and, on the other hand, to speak of health as poor, bad, miserable, etc., would involve a solecism. In short, health and disease are so imperceptibly merged into each other, that the line of demarcation cannot be drawn with precision. And this is true of other departments of knowledge. It is not easy, for example, to settle upon the characters which mark the boundaries of the animal and the vegetable kingdom. But as there is rarely any practical embarrassment in distinguishing an animal from a vegetable, so with regard to health, if an important disease of any kind exist, the fact of its existence is in most cases sufficiently obvious. If, however, it be desirable to define disease otherwise than by saying that it is the absence or deficiency of health, the definition proposed by Chomel is, perhaps, as good as any other. According to this author, disease may be defined to be *a notable disorder affecting more or less of the constituent parts of the living organism, as regards either their material constitution or the exercise of their functions.*[1]

[1] "Un désordre notable survenu, soit dans la disposition matérielle des parties constituentes, du corps vivant, soit dans l'exercise des fonctions." For an enumeration of the various definitions proposed by different writers, and some excellent remarks on the subject, this author may be consulted: Elémens de Pathologie Générale, quatrième édition.

By regarding disease as the absence or deficiency of health, we are led to the consideration of the relationship of Pathology to Physiology. Physiology studies the operations which go on in the healthy organism. The morbid conditions which are the subject of pathological study are these operations disordered or perverted. Pathology has been called morbid physiology. Both are, in fact, parts of one science, the science of life, or biology. Both are alike occupied with vital properties, actions, and processes, the difference being that physiology investigates them under the circumstances of health, and pathology under the circumstances of disease. The division is arbitrary, although sufficiently marked and appropriate.

Such being the relationship of pathology to physiology, it might be expected that the former would advance in proportion to the progress of the latter. This is measurably true. While our knowledge of pathological conditions does not consist of deductions from what is known of the operations within the organism in health, but is derived from the direct study of disease, every important physiological discovery sheds more or less light on the department of pathology. In striving to penetrate into the nature of morbid conditions, it is evident that the chief difficulty arises from the imperfection of our knowledge of the properties, actions, and processes of health. There will be frequent occasions, in the progress of this work, to remark that the pathologist may expect to be better able to explain the phenomena of disease, when the physiologist has succeeded in elucidating more fully the phenomena of health.

In proceeding now to present the outlines of medicine, the aim of the author will be to give a truthful representation of pathological knowledge as it exists at the present moment. The progress of pathological knowledge has wrought, within the few past years, much change in both the principles and practice of medicine. Concerning further progress and its effects, it would be in vain to speculate; but it is hardly to be expected that a faithful exposition of medicine as it exists at the present moment will serve as a lasting guide for the student and practitioner. And in the study of medicine, next in importance to an acquaintance with what is actually known, is a just appreciation of the limits of our present knowledge. The latter is often important as regards its bearing on the treatment of disease, and it conduces to a condition of mind most favorable for either contributing to, or keeping pace with, the continued progress of knowledge.

PART I.

PRINCIPLES OF MEDICINE, OR GENERAL PATHOLOGY.

CHAPTER I.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY.

Congenital Malformations—Three classes of Lesions, viz., Lesions of Quantity, of Consistence, and of Composition—Hypertrophy and Atrophy, Lesions of Quantity—Hypertrophy—True and False Hypertrophy—Atrophy—Atrophy with Increase and with Diminution of Volume—Lesions of Consistence—Induration—Softening—Inflammatory and Non-inflammatory Softening.

A MULTIPLICITY of anomalies, occurring during intra-uterine life, are embraced under the name *congenital malformations*. They consist of either the malposition, the absence, or the incompleteness of organs, deficiency or redundancy as regards bulk, deviations of form, supernumerary parts, want of the normal connection between parts, etc. They may be due to intrinsic defects in the ovum, to arrested or obstructed development from various extrinsic causes, and in some instances they arise from the diseases to which the fœtus is liable. Passing by congenital malformations, this chapter will be devoted to certain definitions, distinctions, and general considerations relating to the changes in the solid parts, or lesions, which occur, as results of disease, after birth.

Anatomical changes in solid parts are recognized by means of morbid appearances, some of which are evident to the naked eye, and others require for their detection microscopical examination. The changes in color, form, etc., appreciable with the naked eye, constitute what are called the *gross appearances* of disease, and those discovered by the microscope are called the *microscopical characters*. Certain changes are determined by the touch; changes as regards softness or density, smoothness or roughness, alterations of form, etc. Increase and diminution in weight are also to be taken into account.

It is hardly necessary to add, but the fact is not always sufficiently considered, that the student must become familiar with the normal appearances (gross and microscopical) of the different structures and organs of the body before he is qualified to recognize and appreciate the alterations which proceed from disease.

Anatomical changes, or lesions, may be arranged into three classes, as follows: 1st. Lesions of quantity; 2d. Lesions of consistence; and 3d. Lesions of composition. Lesions of quantity are of two kinds, viz.: *first*, a morbid increase, and, *second*, a morbid diminution of the substance or substances proper to the part affected. In the lesions which properly belong to this class the composition of the parts affected remains unchanged. The normal structure is unaffected; the abnormal change is purely quantitative, not qualitative. A morbid increase of substance is called *hyper-*

trophy; ὑπερ, τροφη (nourishment). A morbid diminution of substance is called *atrophy*, α, τροφη. These two lesions of quantity claim separate consideration.

Hypertrophy—Hyperplasia.

The development of the different component parts of the body, the cessation of the growth of parts after an inherent principle of limitation, and the preservation of a definite size and form during the constant molecular changes incident to nutrition, are physiological mysteries which we cannot, with our present knowledge, undertake to explain. Hypertrophy involves an abnormal activity of nutrition, and an exaggeration of that principle or force which determines the normal size and form of the different parts of the body. The term hypertrophy is properly applied to enlargement from an increase of the normal materials of the parts affected, their structure remaining normal; in other words, the lesion consists in augmentation without any other change. Parts which become enlarged in consequence of a deposit of materials foreign to their normal composition, or from a disproportionate excess of certain of their normal constituents, or in which a structural change has taken place, are not, properly speaking, hypertrophied. For example, the liver augmented in size from fatty deposit, carcinoma, etc., is not an example of hypertrophy. The term *hypertrophy* has been applied to enlargement accompanied with change in composition or structure. *True hypertrophy* of a part proceeds from an excess of appropriation, by the part, of nutritive supplies, the process of nutrition being only increased, not perverted, whereas in false hypertrophy there is a morbid perversion of this process.

The enlargement of an organ, without the deposit of new material or structural change, does not always proceed from hyper-nutrition, and then it does not constitute hypertrophy. The hollow viscera—heart, stomach, bladder, etc.—may acquire more or less increase of volume from dilatation, the amount of substance being not greater, and perhaps less, than normal. Hence, it would not be a correct definition of hypertrophy to say that it consists in augmented volume without change in composition or structure.

True hypertrophy of a part generally proceeds from exaggerated and prolonged increase of the function of the part. Of the organs of the body, the heart is most frequently, perhaps, the seat of this lesion. And in the great majority of cases of hypertrophy of the heart, the enlargement is due to valvular lesions which, by interfering with the circulation of blood through this organ, induce a permanently increased power of its muscular action. The muscular walls, under these circumstances, increase in bulk by growth precisely as the voluntary muscles become enlarged when they are persistingly exercised. The heart may become hypertrophied to such an extent that it is five or six times heavier and larger than in health, yet there is a limit to its hypertrophic enlargement; that is, the increased growth does not go on indefinitely, but of necessity ceases after reaching a certain point of limitation, which point varies in different persons. Hypertrophy of the muscular tunic of the bladder in cases of long-continued urethral obstruction also illustrates the production of this lesion by prolonged increase of function.

It has been a much mooted question whether, in muscular hypertrophy, the increase of size is owing exclusively to enlargement of the primitive fibrillæ, or whether new fibrillæ are produced. Pathological authorities still differ in opinion on this point. It would seem to be probable, if not

certain, that hypertrophy of the involuntary or unstriped muscular structure may involve the production of new fibres. Of this we have a physiological type in the development of the muscular walls of the uterus during gestation.

Hypertrophy of one of the kidneys sometimes ensues when the function of the other is either lost or greatly impaired. This is found to be the result of the removal of one of the kidneys in an inferior animal; under these circumstances the task of secreting the urine falls upon a single organ, its functional activity is doubled, and, as a result, the organ becomes enlarged. The enlargement in this case is abnormal, but, if it confer on the organ an increased capacity of secretion, it is a conservative lesion, that is, it conduces to the welfare of the body. This is certainly true of the examples of hypertrophy previously cited. Hypertrophic enlargement of the heart occurring in connection with valvular lesions is an important provision against evils which would otherwise ensue more quickly than they do. In this sense it is conservative. And this statement holds good with respect to hypertrophy of the muscular tunic of the bladder in cases of urethral obstruction. It is not an object of treatment in such instances to endeavor to remove or diminish the hypertrophy so long as circumstances giving rise to it continue in operation.

The hyper-nutrition giving rise to hypertrophy does not always proceed from protracted, excessive functional exertion. In other than muscular and glandular structures, it may result from an undue determination of blood, from any cause, to the part affected. It may result from inflammation of a part. Hypertrophy of the fibrous and areolar tissues, perhaps, generally proceeds from inflammation. Hypertrophy of the adipose tissue, constituting corpulence, involves a general condition or diathesis, of which the undue growth of this tissue is a manifestation or local expression.

A distinction is made by Virchow between true or simple hypertrophy and enlargement due to multiplication of the anatomical elements of the affected parts. The latter kind of enlargement he distinguishes by the term *hyperplasia*. In hypertrophy, according to this distinction, there is simply swelling of structures from the addition of nutritive material. In hyperplasia new anatomical elements are generated, but without any other change than that relating to their number. Thus, a muscle enlarged by the increase of the size of the primitive fibrillæ would be, in this sense of the term, hypertrophied; but the enlargement is hyperplastic if due to the production of new fibrillæ. This distinction is pathologically just.

Atrophy.

The term atrophy expresses a condition, as regards nutrition, the reverse of that expressed by the term hypertrophy. In hypertrophy the normal balance between the appropriation of nutritive material and destructive assimilation in the part or parts affected is disturbed by the former being in excess. In atrophy the destructive assimilation goes on, but the appropriation of fresh supplies is either suspended or diminished; hence, loss of the substance proper to the part ensues, and the structures composing the affected parts undergo waste. Unless the space which was occupied by the matter removed be filled with a morbid product of some kind, diminution of volume or bulk and of weight characterizes atrophy. Atrophy, however, may exist, not only without reduction, but with more or less increase, of size. For example, cirrhosis of the liver leads to atrophy of the proper tissue or parenchyma of this organ, and usually to diminu-

tion of its volume; but in some cases, in conjunction with the atrophy due to the cirrhosis, there is a deposit of fat or some other material, the presence of which renders the organ as large as, or larger than, in health. Under these circumstances the organ is not less the seat of atrophy, although its size be not reduced, but even increased. Atrophy, thus, may exist with false hypertrophy. To cite another illustration, the heart is not unfrequently enlarged in consequence of the substitution of fat for the muscular substance contained within the myolemma, constituting what is called fatty degeneration. This substitution of fat involves atrophy of the muscular structure. Atrophy thus, it will be perceived, implies wasting of the tissue proper to the parts affected, either with or without a deposit of matter which alters the composition of the parts, and which, in proportion to its quantity, affects the volume.

Atrophy with diminution of volume is strikingly illustrated in that remarkable affection known as progressive muscular atrophy, in which different portions of the muscular system successively become greatly attenuated. It is illustrated in that variety of chronic disease of the kidneys in which these organs are greatly reduced in size. The liver much contracted from cirrhosis furnishes another striking illustration. Atrophy of membranous parts is illustrated by cases in which the valves of the heart become extremely thin and delicate, so that rupture is liable to occur. The walls of hollow viscera, the heart, stomach, etc., may be rendered abnormally thin by atrophy, either with or without increased volume by dilatation. Atrophy affecting the greater part of the body, and more especially the adipose tissue, constitutes the emaciation occurring in pulmonary tuberculosis and other chronic affections. This general atrophy is expressed by the terms phthisis, consumption, and marasmus. Progressive atrophy of most of the organs of the body, excepting the heart, is incident to old age, and is distinguished as senile atrophy.

Of the circumstances which give rise to atrophy, one is functional disuse of the part or parts affected. Atrophy induced in this way is seen in the wasted condition of muscles which have remained for a long time quiescent in cases of paralysis and chronic rheumatism. The other tissues, and even the bones, in these cases, become atrophied. Diminished supply of arterial blood is another causative circumstance. The ligature of an important distributing artery may produce wasting of parts which are thus deprived of a normal quantity of blood. Mechanical pressure is another circumstance. An aneurismal or other internal tumor which progressively increases in size occasions atrophy of the parts with which it is in contact. The atrophy in cirrhosis of the liver is probably caused by the pressure upon the lobules of this organ of a morbid product situated within the interlobular spaces. The general atrophy which occurs in pulmonary tuberculosis or other affections, and senile atrophy, are due to constitutional states unfavorable to nutrition.

As contrasted with hypertrophy, atrophic lesions are rarely, if ever, conservative; that is, they are not, as are hypertrophic lesions in most cases, conducive to the welfare of the economy in view of the circumstances under which they occur.

Morbid alterations as regards the consistence of parts constitute the second of the three classes of anatomical changes or lesions. These alterations are of two kinds, namely, increased consistence or induration, and diminished consistence or softening. Both induration and softening are frequently incidental to palpable changes in the composition of parts, and, under these circumstances, they are not properly included in the

second class of lesions, but they belong to the third class. This second class embraces induration and softening, not occurring as results of morbid deposits of various kinds, degenerations of structure, acute inflammatory processes, etc., but constituting, in themselves, the primary, palpable lesions. As thus restricted, examples of each are not very numerous.

Induration.

A part is indurated when its density and firmness are abnormally increased. As just stated, this physical change is generally incidental to manifest changes of composition or structure involving usually the presence of morbid products in the parts affected. Thus, in cirrhosis of the liver, the morbid production of fibroid tissue in the interlobular spaces gives to this organ an abnormal density and firmness. The same is true of that variety of degeneration of the kidney characterized by contraction and hardness. In these and similar instances, induration is a result of other palpable changes. Induration as a sole or chief lesion occurs when certain parts are condensed by pressure, and when they are deprived, to a greater or less extent, of their normal quantity of liquid.

Induration due to condensation is exemplified, in a striking manner, by the carnified lung in cases of pleuritis with large effusion. The lung, in these cases, is compressed into a small, compact mass, bearing more resemblance to flesh than to the pulmonary organ in its natural condition, and hence it is said to be carnified. Yet the composition and structure are not materially altered; by means of insufflation after death, the condensed lung may be restored to its normal condition, and this also occurs during life when the liquid effusion is absorbed. A similar condensation of pulmonary lobules takes place, from collapse, in certain of the cases heretofore embraced under the name lobular pneumonia. Induration from deficiency of liquid is exemplified by the abnormal density and firmness of the brain and other organs after death from epidemic cholera, the loss of liquid in this disease being due to the intestinal transudation.

Induration of the substance of the brain has been observed in cases of acute and chronic lead poisoning; and the brain in these cases has been found to contain the sulphate of lead. The term *sclerosis* (σκληρος, hard) is used to denote induration of parts generally from hyperplasia of connective tissue, or a fibroid product.

Softening.

A part is softened when its density and firmness are abnormally diminished. The softening may be greater or less in degree. Portions of the brain or spinal cord are sometimes softened to liquefaction, but then, of course, there is total loss of structure, or disorganization. Softening, in most cases, is incidental to some manifest change of composition or structure, or it is an element of certain morbid processes, namely, inflammation and gangrene. An example of softening as incidental to an inflammatory deposit is afforded in pneumonitis. In the second stage of this disease the affected portion of lung, although solidified (hepatized), has less firmness than in health. It breaks down more readily under pressure with the finger than healthy lung, and hence, is said to be more *friable*. The friability is still more marked in the stage of purulent infiltration, the softening then becoming so great that the structure gives way under moderate or slight pressure of the finger.

Softening of the brain or spinal cord is a result of inflammation extend-

ing from the meninges, developed around a clot of blood or a tumor of some kind, or originating spontaneously within these nervous centres; but softening occurs here independently of inflammation, the cohesion of the nervous filaments and vesicles being diminished by defective nutrition, dependent on a deficient supply of blood or other causes. Non-inflammatory softening of the brain is frequently associated with degenerative changes of the coats of the cerebral arteries, in consequence of which the distribution of blood is impeded and nutrition impaired; and it occurs from arterial obstruction caused either by a mass of fibrin or a vegetation derived from the left side of the heart, constituting what is called an *embolus* or plug, or from coagulation of blood at the seat of the obstruction, when it is called a *thrombus*. Softening, as thus produced, as will be hereafter seen, is involved in certain cases of apoplexy and paralysis. If the softening be considerable, it involves a change in composition; there is either a decomposition analogous to gangrene, or the change consists in a granulo-fatty degeneration.

Softening is incidental to inflammation affecting any of the tissues. This result is especially marked in inflammation of the mucous membranes. These are sometimes completely disorganized and reduced to a pulp, so that portions are mechanically removed by the attrition of substances moving over their surfaces. This is seen in examinations after death in cases of dysentery. When the degree of softening of the mucous membranes is less, it is shown by the inability of tearing small portions away in strips with the forceps. Non-inflammatory softening of these membranes, elsewhere than in the stomach and small intestines, is certainly rare. And in the stomach, especially, the softening found after death, when inflammation has not existed, is, in most cases, probably, a post-mortem change due to the dissolving action of the gastric juice. Softening from the latter cause may exist in a great degree, affecting all the coats of the stomach, leading to perforation and softening of the adjacent viscera, in cases of death taking place suddenly while the process of digestion was going on. If the protection of the stomach against the action of the gastric juice, in life, depends, as considered by Bernard, on the presence of mucus, it is not improbable that softening from the same cause may sometimes take place after death, owing to deficiency of the secretion of mucus.

Softening occurs not only ir parts which are inflamed, but in proximate tissues not involved in the inflammation. Thus, in serous inflammations, the subserous areolar tissue loses its normal firmness and becomes brittle, so that the membrane is detached much more easily than in its healthy condition.

Softening of the muscular tissue is incidental to fatty degeneration, but it occurs, as the chief or sole palpable change in the heart, in certain cases of typhus and typhoid fever. Softening of the spleen, occurring in these fevers, is also an example of this change occurring without inflammation, or any well-defined change in composition or structure.

The softening which is non-inflammatory and independent of other palpable changes is, in general, referable to a defect in the nutrition of the affected parts. This defect may be dependent on circumstances limited to the parts, as when cerebral softening arises from arterial obstruction; or it may proceed from a general condition, involving a deficiency of nutritive supplies in the blood, as when softening of the heart occurs in typhus or typhoid fever. If the softening consist only in diminished coherence of the component anatomical elements of the parts, without being sufficient to occasion disorganization, it is not irremediable nor

necessarily even a grave lesion. Softening of the heart and spleen doubtless occurs in cases of fever which end in complete recovery; and it is not improbable that in certain cases of softening of the brain, dependent on a temporary defect of arterial supply, as when it is occasioned by an embolus, the normal consistence may be restored after the re-establishment of the circulation.

To softening in a degree involving disorganization, resulting from the death and mortification of the part affected, Virchow applies the term *necrobiosis*.

CHAPTER II.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY— (CONTINUED.)

Lesions of Composition—Exudations and Transudations—Fibrinous Exudation or Coagulable Lymph—Tubercle—Scrofula—Carcinoma or Cancer—Typhoid Deposit.

ALTERATIONS as regards the composition of parts constitute the third class of anatomical changes. The lesions embraced in this class are more numerous and important than those included in the preceding classes. Of the changes belonging to this class, I shall notice those which are of importance in relation to medicine as distinguished from surgery, presenting, briefly, certain distinctions, etc., which should be understood by way of preparation for entering on the study of individual diseases. It does not fall within the scope of this work to enter into a full account of the various alterations which will be noticed. The student is expected, in addition to the outlines here presented, to pursue this part of the subject more fully by means of works which treat at length of morbid anatomy, including histology, and of general pathology.

It is appropriate to reckon among changes in composition, not only perversions of structure, but changes which consist in the addition of abnormal products, either solid or liquid, the tissues of the parts remaining unaffected. For example, the infiltration of liquid into the interstices of a part alters its composition, although there be no structural change in the part. To cite another example, in the hepatization which takes place in pneumonitis, there is a solid deposit within the air-cells, and the presence of this deposit alters, for the time being, the physical condition of the affected portion of lung. The composition of the lung is in fact changed. But the structure of the lung remains intact, and as soon as the morbid deposit disappears, the normal condition of the lung is restored. In other examples, for instance, when the composition of the lungs is altered by the addition of the tuberculous products, the presence of these, and the changes which they undergo, lead to more or less injury or destruction of the pulmonary structure. In this instance, however, the morbid products were not, at the outset, substituted for, but added to, the anatomical constituents of the part, and the damage which is occasioned is a result more or less remote. On the other hand, there are changes in which morbid products supplant the substance proper to the parts affected, and thus involve perversions of structure. Here is an important

distinction as regards changes in composition. Changes in composition may consist, then, 1st, in the presence of morbid products not involving primarily, or of necessity, change of structure; or, 2d, they may consist in structural alterations. The latter are commonly called degenerations. Changes which do not affect the tissues entering the composition of parts, are not necessarily destructive; they may be temporary, and, after their disappearance, the parts may be in no wise damaged, as in the example of pneumonitis. But perversions of structure or degenerations involve, from the outset, disorganization of parts, and, in general, are permanent or incurable.

A distinction is to be made between morbid products which become solid or semi-solid, and those which remain in a liquid state. For the sake of distinction, the term *exudations* should be restricted to solid or semi-solid products. On the other hand, the term *transudations* may be applied to constituents of the blood which escape through the coats of the vessels and preserve their liquid state. These terms will be used hereafter as now defined. An exudation is a solid or semi-solid morbid product derived from the blood; a transudation is a liquid effusion constituting, when retained in any part, a dropsy.[1] The materials composing exudations, as well as transudations, of course, are derived from the blood, and are in a liquid form within the bloodvessels. In the exudative process there is, therefore, a derivation from the blood of certain of its constituents which assume a solid or semi-solid form after leaving the vessels. Now, regarding the act of exudation, there are certain pathological questions as yet unsettled. Does an exudation occur in consequence of a prior blood-change, or does it depend on a process pertaining to the part in which the exudation takes place; or, again, are a blood-change and a local process conjointly involved? The doctrine which has been, and is still, held by many pathologists is, that exudations represent certain morbid conditions of the blood; and that they consist of blood-constituents which, after escaping through the coats of the vessels, undergo coagulation and subsequent changes. On the other hand, according to the so-called cellular pathology, now accepted by many, the act of exudation is exclusively a local process taking place through the agency of cells. Whatever pathological views may be entertained, the name exudation is appropriate enough as applied to a morbid product, solid or semi-solid, which is added to the tissues of a part, and which is distinct from either a morbid growth or the formation of new tissue. The term product will be frequently used as applicable alike to a morbid deposit and a morbid growth.

With these explanations, the consideration of the anatomical changes belonging to the third class will embrace exudations, transudations, or liquid effusions, lesions of structure or degenerations; and added to these are new formations or morbid growths, pneumatoses, or the abnormal presence of air or gas in parts, and parasitic productions, vegetable and animal. The remainder of this chapter will be devoted to anatomical changes dependent on exudations.

Fibrinous Exudation.

An exudation which forms an important event in the natural history of certain inflammations is that distinguished as *fibrinous*. By the older writers it was called *coagulable lymph*, and it is still commonly known by

[1] This distinction between an exudation and a transudation is not made by all writers. It was made especially by Lehmann.

that name. Bennett calls it simple exudation. It is generally considered to be essentially the fibrin of the blood, or the blood-plasma, either simple or more or less modified, in a coagulated state; the liquor sanguinis, which contains fibrin in a liquid state, exudes, and the fibrin coagulating constitutes the deposit. It may also be distinguished as *inflammatory exudation*. It is perhaps correct to state that it is always a product of inflammation; that is, it occurs only as a result of an inflammatory process. It is the criterion by which the existence of inflammation in certain structures is determined; its presence is proof of inflammation in these structures, and, if not found on examination after death, adequate evidence of inflammation having existed is wanting. It belongs especially to inflammation of the serous membranes, and will be found to constitute an important part of the history of pleuritis, pericarditis, peritonitis, etc.

Examined shortly after it has exuded upon a serous surface, it presents the appearance of a semi-transparent, gelatinous semi-solid. Examined microscopically, it is found to contain minute filaments, such as are found in the coagulated fibrin of the blood, intermingled with corpuscles, to which various names have been applied, namely, plastic, pyoid, exudation-corpuscles, etc. The latter are to be considered as belonging to a class of corpuscles called *leucocytes*, embracing pus-globules, the white globules of the blood, mucous corpuscles, etc., all of which, according to microscopical observers, are essentially identical. At a later period the exudation becomes more solid, frequently forming a thick, dense layer, adherent mechanically to the serous surface, and having distinctly a fibrous arrangement. Detached and peeled off, it resembles a membrane, and is commonly called a false membrane. Not unfrequently the exudation forms a series of layers, which may be separated from each other like the coats of an onion. The coagulation of the fibrin contained in the exuded liquor sanguinis leaves a certain amount of serous liquid, which, in serous inflammations, accumulates within the serous sac, so that, in examinations after death, more or less liquid is usually found together with the coagulable lymph. Flakes of lymph, in greater or less abundance, are contained in the liquid, and the latter is turbid, instead of being transparent as in purely dropsical effusions.

In the progress toward recovery, the liquid contained within the serous sac is absorbed. The serous surfaces then coming into contact may be agglutinated by means of the intermediate lymph. The latter is absorbed more slowly. A true membranous or organized structure subsequently becomes developed, which is the medium of the permanent adhesions resulting from inflammation of serous structures. An unfavorable progress is characterized by the serum and lymph remaining unchanged for an indefinite period, or by the production in large quantity of the well-known liquid called pus, which is characterized by the presence of corpuscular bodies called pus-globules or leucocytes.

Selecting serous inflammations as typical, because they are distinguished by the constancy and abundance of inflammatory exudation, the brief description just given is an epitome of the natural history of this morbid product. But considerable variations are observed in different cases of serous inflammations. The relative proportions of lymph and serum vary widely. The quantity of lymph may be abundant or quite small, and the same is true of the liquid effusion. The constitution of the lymph varies. The formation of fibrillæ, or the fibrillation, may be greater or less, and the corpuscular constituents, or leucocytes, may be few or abundant. Paget reckons two varieties of lymph, one variety being characterized by the predominance of fibrillæ and the other by the

abundance of corpuscles, with a small quantity of fibrillæ. The former he calls *fibrinous*, and the latter *corpuscular*, lymph. The fibrinous variety he regards as favorable for the production of organized tissue, and hence it is called plastic, while the corpuscular variety tends to the production of pus or suppuration.

The ordinary product of the inflammation of mucous membranes is mucus variously modified, and containing, in more or less abundance, the corpuscular bodies known as mucous globules, which are essentially identical with pus-globules, or, in other words, belong in the category of leucocytes. Exceptionally, however, fibrinous exudation occurs on a mucous surface, and, disposed in the form of a false membrane, presents characters analogous to those which belong to the exudation in serous inflammations. This constitutes the characteristic feature of the inflammation of the larynx and trachea, sometimes extending to the bronchial tubes, in true croup, and of the inflammation of the fauces, air-passages, and in other situations, in the epidemic disease called diphtheria. Inflammation of a mucous surface or of the skin, when characterized by fibrinous exudation, is frequently distinguished as *diphtheritic*, after a term introduced by Bretonneau. Occasionally in bronchitis a false membrane is formed, and this variety of the disease is called, incorrectly, *plastic* bronchitis. Fibrinous exudation is not uncommon in cases of dysentery. The formation of new tissue does not take place in connection with a fibrinous exudation on mucous surfaces. The false membrane, in all cases, in the course of a few days becomes detached by a suppurative process beneath it, and is thrown off. This is the basis of a division, by Rokitansky, of inflammatory exudation into *croupous* and *plastic*. The term plastic, frequently applied to inflammatory exudation, denotes its capacity of developing within it organized structures. This is also expressed by the term *blastema*, which was formerly applied to inflammatory exudation. The term *cytoblastema*, which has the same application, denotes the development of cell-formations within the exudation. These two terms (blastema and cytoblastema) have been used to denote an amorphous liquid in which anatomical elements, either cells or tissues, were supposed to be produced by auto-genesis or spontaneous generation. In pneumonitis an inflammatory exudation within the air-cells solidifies the lung, giving rise to the condition called hepatization. In this situation organic tissue is not formed, and the exudation is removed by absorption. A very small proportion, sometimes none whatever, is expectorated, and clinical observation shows that the large amount of exudation which takes place in this disease may be absorbed very rapidly, being all removed in the course of a few days. In other parenchymatous inflammations, fibrinous exudation sometimes takes place and is infiltrated among the component tissues. In the brain and spinal cord it is presented in the form of minute granules with which pus-globules or leucocytes may be commingled. These products, in connection with softening, show the latter to be due to inflammation. In other parts, the presence of fibrinous exudation, which may persist without metamorphosis or change for an indefinite period, involves enlargement by false hypertrophy and induration; or it may sooner or later lead to suppuration; or, leading to the development of fibroid tissue, it may produce atrophy and disorganization, as is seen in cirrhosis of the liver and the hard contracted kidney.

It is thus seen that the fibrinous exudation in different situations, and in the same situation in different cases, presents variations as regards its constitution, the metamorphoses of which it is the seat, its behavior (to borrow a metaphorical term from the chemist), and its consequences.

Our present knowledge does not enable us to say to what extent these diversities may be due to primary, essential differences, that is, differences pertaining to the exudation itself, or how much is attributable to circumstances connected with the exuding process, or again, the amount of influence exerted by the surrounding parts upon the exudation after it has taken place. Much undoubtedly depends on the situation of the exudation; for example, it is never the seat of a newly-formed organized structure on a mucous surface. But it remains to account for the variations which are shown in different cases in the same situation, for instance on a serous surface. Whether these variations depend on morbid conditions of the blood, or on local actions involved in inflammation, is at present an unsettled question.

A pathological question which must still be considered as *sub judice* relates to the development of organized tissue, and the production of corpuscular bodies in connection with fibrinous exudation; in other words, to this exudation regarded as a blastema and as a cytoblastema. The question is, whether the newly-developed tissues and pus-globules, which are undoubtedly produced, are products of a metamorphosis of the coagulated fibrin; in other words, is coagulable lymph converted into living structure, taking on organization, and is it transformed into pus? The view taken by Paget, and heretofore generally received by pathologists, is, that the coagulated fibrin or lymph is organizable, *i. e.*, capable of being transformed into organized living structures; and also that it is formed into pus. The term plastic is used to distinguish the kind of lymph which is supposed to be especially prone to organization. On the other hand, Robin and others regard coagulable lymph in the light of an extraneous product, denying its capability of being transformed into either organized tissues or pus. According to the latter view, it either remains without essential change, or it is exfoliated, or it is absorbed, newly-formed tissue being produced by molecular combination during the act of exudation; consequently, alone it has no claim to be called a blastema, nor does it take part in the generation and multiplication of pus-globules or leucocytes. According to the cellular pathology of Virchow, morphological products, that is, cells or tissues, are never spontaneously generated; and hence, a blastema or a cytoblastema has no existence. The doctrine of Virchow is that all organized forms are produced by the proliferation or multiplication of cells. This doctrine is formularized by the phrase *omnis cellula e cellulâ*. On the other hand, the doctrine advocated by Bennett, Robin, and others is, that cells and tissues may be produced by a formative force inherent in molecules and independent of cell-proliferation. A liquid in which such a force is exerted is a blastema or a cytoblastema. This is called by Bennett the *molecular theory*. This theory does not deny that morphological productions take place by the proliferation of cells, but, denying that tissues and cells are exclusively thus produced, it accounts for the development of both, to a greater or less extent, by the arrangement of molecules.

Tubercle.

The term *tubercle*, as generally used, embraces morbid products of great importance in view of the frequency of their occurrence and the extent to which they contribute to mortality. To the affections characterized by these products is applied the name *tuberculosis;* as, tuberculosis of the lungs, or pulmonary tuberculosis, tuberculosis of the liver, etc.

They are also called tuberculous affections. The products occur in various situations, but especially in the pulmonary organs.

Two products especially have been embraced under the name tubercle. One of these is the product known as tuberculous, fibro-plastic, semi-transparent, or miliary granulations, and the granulations of Bayle. This product may be conveniently distinguished as *gray tubercle*. It is presented in the form of small, spherical bodies of a grayish color, semi-transparent, and of considerable resistance to pressure, the size being generally that of millet or hemp-seeds; but sometimes they are so minute as to be scarcely visible with the naked eye. They may be more or less abundant. Existing in the lungs in immense number, they characterize the affection called *acute phthisis*, life being destroyed by this affection in consequence of their accumulation sufficiently to compromise, to a fatal extent, the function of respiration. They occur elsewhere than in the pulmonary organs, being found in the liver, spleen, and other parts, as well as in the lungs. They give rise to the form of peritonitis called tuberculous, and to the so-called tuberculous meningitis of children. Examined microscopically, they are found to consist of granules with minute free nuclei and cells, described by Robin under the name cytoblastions. According to Robin, cytoblastions are found in the lungs and in other parts in health; hence, he regards the gray tubercle as due to a hypergenesis of normal anatomical elements. Virchow considers this tuberculous product as a morbid growth or a neoplasm due to proliferation of the connective tissue cells. If the latter view be correct, the product is not an exudation in the sense in which this term has been defined.[1] By Bayle and others, gray tubercles were supposed to remain indefinitely without any notable change; but late microscopical researches seem to show that, after a time, they become opaque and soften, undergoing a granular and fatty metamorphosis. According to these researches, the primary seat of the gray tubercles in the lungs is without the air-cells in the interstitial tissue around the small vessels and capillaries. They adhere so closely to the tissues that they are detached with considerable difficulty. Following Bayle, who first distinctly described these bodies under the name miliary granulations, some pathologists have denied their tuberculous character, regarding the product to be presently noticed as true tubercle; at the present time, however, distinguished German and French pathologists entertain an opinion directly the reverse of this, regarding the gray tubercle as the only truly tuberculous product.

As already stated, gray tubercles occur in various situations other than the lungs. Of the serous membranes, they occur in the pleura, peritoneum, arachnoid, pericardium, and the tunica vaginalis, enumerating these membranes according to the relative frequency of the occurrence in them. They are, however, not unfrequently found in several or all of these membranes, as well as in other parts, in the same case. They occur in the mucous membrane of the small and large intestine; in the trachea, larynx, and bronchial tubes, and, in some very rare instances, in the stomach and œsophagus. They also occur in the lymphatic glands and vessels; in the liver, kidneys, and testicles, and in the bones. They have not been found in the muscular, cartilaginous, and tendinous structures, nor in the skin, nor in the mammary gland. Their occurrence in the salivary glands and pancreas is doubtful.

They are to be distinguished from cancerous granulations, coagulable lymph in a granular form, syphilitic or gummy tubercles, and the tuber-

[1] *Vide* page 32.

cles of glanders. For the differential characters involved in this discrimination, the reader is referred to works treating of morbid histology.

The other product embraced under the name tubercle, the product which by many has been heretofore considered as alone truly tuberculous, is commonly known as *yellow tubercle*. This is an exudation which, in the lungs, takes place within the air-cells or pulmonary alveoli. It is presented either in the form of small, isolated, round masses, constituting a variety of the so-called miliary tubercles; or it accumulates so as to form collections varying in size from a filbert to an orange, and these may be more or less numerous. The latter form is distinguished as infiltrated tubercle. In the state called crude tubercle, it is opaque; it has a yellowish color, and is of a cheesy consistence, being easily broken down with the fingers, *i. e.*, friable. Examined microscopically, it is found to consist of amorphous granules, inclosing, in more or less abundance, corpuscular bodies which have been called tuberculous corpuscles. These were described by Lebert as specific morphological elements of tubercle. According to Virchow, they are the nuclei or fragments of epithelium which have undergone a granular and fatty metamorphosis. They are round, oval, or polyhedral, granular in appearance, devoid of nuclei or nucleoli, unaffected by water, rendered transparent by acetic acid, and extremely small, their average diameter being from $\frac{1}{2000}$ to $\frac{1}{1200}$ of an inch. According to Robin, they differ essentially from the cells, which he calls cytoblastions, found in gray tubercle. As regards chemical composition, this morbid growth consists of albuminous matter combined with fatty granules, crystals of cholesterin, and certain earthy salts, the latter being chiefly the phosphate and carbonate of lime. The relative proportion of animal matter and earthy salts varies in different specimens.

After a variable period, the masses or collections undergo softening, attributable partly to intrinsic changes, and, in part, to the permeation of fluid derived from the surrounding tissue; and they are at length converted into a creamy liquid, having a resemblance to pus. Microscopical examination now shows granular matter, the tuberculous corpuscles few in number, pus-globules or leucocytes, elastic fibres from the pulmonary structures, fatty granules, bronchial epithelium, and blood-crystals. Sooner or later these tuberculous abscesses, as they have been called, the *vomicæ* of the older writers, open into the bronchial tubes. Exceptionally, they open into the pleural sac. These changes involve destruction of the pulmonary structure proportionate to the amount of the morbid product.

Both these morbid products are never the seat of newly formed tissue. They are not readily absorbed, but there are grounds for believing that the latter is sometimes completely removed by absorption. The animal portion may be absorbed, the mineral portion remaining, and in this way may be explained, at least in part, the formation of small calcareous masses, or calculi, not unfrequently found after-death, and which are sometimes expectorated. When the process of absorption is going on, the tuberculous affection is said to be *retrogressive*, and the calculi formed in the lungs have been called *obsolete tubercles*.

The relationship between the two products just described, has been heretofore much discussed, and at the present moment is under discussion. Laennec, rejecting the doctine of Bayle, that they are essentially different morbid products, considered each as composed of the same substance, the tuberculous matter, which is at first gray, and afterward becomes yellow tubercle. This view was generally adopted, until the microscope came to be employed in pathological researches. Among

microscopical observers there has been, and still is, a difference of opinion respecting the identity of the two products, none doubting, however, the existence of a relationship between them. Without entering into historical details, I shall confine myself to a concise statement of certain recent views, which, although adopted by many pathologists, should be considered as, at present, *sub judice*. Following Virchow, the gray tubercle, meaning, by this term, the semi-transparent granulations of Bayle, is considered as the only true tuberculous product. Yellow tubercle is considered as a result of a degenerative change of different morbid products, inclusive of the gray tubercle; but, for the most part, it consists of the products of inflammation, which, in the lungs, are seated within the air-cells, these products having undergone what is called a cheesy metamorphosis. The so-called yellow tubercle, as produced by the cheesy metamorphosis of inflammatory exudation, is not entitled to be called tuberculous, and the gray tubercle loses its tuberculous characteristics when it has undergone the granular and fatty degeneration. In some instances the so-called yellow tubercle is simply inspissated or concrete pus.

According to the views just stated, a true tuberculous affection of the lungs, or of any part, involves the production of the gray tubercles or granulations which have been described. Inflammation of the adjacent structures is generally, or frequently, associated; and, in the lungs, the collections of the so-called yellow tubercle, which soften, form abscesses, and result in cavities, denote parenchymatous inflammation, or, in other words, chronic pneumonia. In the majority of the cases of the affection known as chronic pulmonary tuberculosis, the disease is, in fact, chronic pneumonia, associated with the production of the gray granulations. The association, however, of the pneumonia with the granulations is not invariable; the former takes place without the latter, and the latter is not always accompanied by the former. In general, the gravity of the affection is determined by the extent of the coexisting pneumonia; but the granulations existing without pneumonia may give rise to grave symptoms, and produce death by accumulating in immense numbers.

Of the nature of the pathological connection existing between these two products, exactly opposite opinions are held by different pathologists at the present time. By some the gray tubercles are supposed to precede, and give rise to, the yellow product, that is, the pneumonia. Others consider the former as secondary to, and dependent upon, a granulo-fatty or cheesy metamorphosis of either yellow tubercle or analogous products in lymphatic glands within the chest and elsewhere. The production of the gray tubercles, according to the latter opinion, is due to the absorption of matter from degenerated inflammatory products. This doctrine receives some support from the facts recently ascertained with reference to the inoculability of tubercle, to which reference will presently be made. The former opinion, however, seems the most rational of the two. It is supported by the occurrence of gray tubercles, sometimes in great abundance in cases of acute tuberculosis, when no degenerated or cheesy masses are to be found either within the chest or elsewhere. Moreover, in cases of tuberculous meningitis and peritonitis, clinical observation appears to show that inflammation of the serous membrane follows, and is caused by, the production of gray tubercles. A third opinion is perhaps as rational as either of the foregoing opinions, namely, that the two products are dependent neither upon the other, but each upon a causative condition common to both. With our present knowledge, the wisest course is not to adopt unreservedly any of these opinions, but to consider the nature of the pathological connection between the two products as among the

questions to be settled by future researches. It is to be added that some histologists still hold to the essential identity of the two products. It is conceded by those who deny their identity, that the gray tubercles, after they have undergone the granulo-fatty degeneration, cannot be distinguished, by their gross characters, from the so-called yellow tubercles, when these, from their size and form, are miliary; and, also, that the agglomeration and coalescence of gray tubercles may present appearances which render them not distinguishable from the so-called infiltrated tubercle.

The efforts to repudiate yellow tubercle as a tuberculous product, and to substitute the name pneumonia, have given rise to much confusion. To distinguish it from ordinary pneumonia, that is, lobar pneumonia, and also from chronic interstitial pneumonia, various terms are used, such as, chronic lobular pneumonia, chronic catarrhal pneumonia, cheesy pneumonia, and broncho-pneumonia. The propriety of these changes in nomenclature is doubtful, admitting the product to be, in fact, an inflammatory exudation. Admitting this, the behavior of the product differs widely from that of the exudation in both lobar and interstitial pneumonia. The morbid growth in interstitial pneumonia remains without softening, and without leading to structural damage of the pulmonary substance, except from atrophy caused by the pressure of the adventitious tissue. In lobar pneumonia the exudation is absorbed completely, and often with rapidity, the structure of the lungs remaining intact, and the formation of abscesses being extremely rare. On the other hand, the exudation known as yellow infiltrated tubercle is rarely absorbed; and the changes which it undergoes involve destruction, to a greater or less extent, of the parts in which it is seated. In view of these points of difference from other forms of pneumonia, and considering that, if they are not essentially identical, there is a close relationship of some kind existing between the gray and the yellow tubercle, if it be resolved to call the latter a product of pneumonia, it should be distinguished as a tuberculous pneumonia. It is to be added that by some, if not most, pathological histologists, the gray, as well as the yellow, tubercle, is regarded as an inflammatory product; and, according to this view, the former constitutes the anatomical characteristics of a variety of interstitial pneumonia.

Whatever views may be held respecting the relationship between the two products embraced under the name tubercle, and the pathological character of each, that is, of the nature of the process or processes involved in tuberculization, clinical facts which will be stated in treating of pulmonary tuberculosis, in the second part of this work, show that they are both to be considered as the local effect or expression of a morbid constitutional state; in other words, they are the manifestations of a special diathetic condition. Whatever may be this antecedent constitutional state, clinical observation shows that, in many cases at least, it suffices for the occurrence of the tuberculous products, without requiring the co-operation of any local conditions which are discoverable; that is, the occurrence of the products is often the first appreciable local event. Moreover, since the tuberculous products in different situations do not essentially differ, it follows that the local process, or the tuberculization, has more to do with the diathetic condition than with the structure of the part in which it is seated. As already stated, the lungs are the seat of the tuberculous products much oftener than any other part; but not unfrequently they occur, simultaneously or successively, in various situations. The latter is observed in children oftener than in adults. Louis, by means of his statistical researches, ascertained this law, viz., whenever a tuberculous affection occurs in any part of the body, other than the lungs, after fifteen years of age,

pulmonary tuberculosis coexists, and the latter is always the primary manifestation of the tuberculous cachexia. To this law, however, there are some exceptions. Other laws, together with certain questions recently raised relating to etiology and treatment, will be noticed when pulmonary tuberculosis is considered in the second part of this work.

Tubercle was formerly reckoned among morbid products distinguished as *heterologous* or *heteromorphous*, in contradistinction from those called *homomorphous* or *homologous*. The former names denote morbid products which are not identical with, nor analogous to, any of the normal constituents of the organism; the latter names were applied to morbid products which have normal prototypes, that is, they are identical with, or are analogous to, anatomical elements contained in the body in health. Laennec applied the term "accidental products" to those which were considered as heterologous or heteromorphous. But it appears to have been established by microscopical researches that there are no morbid products which are heterologous or heteromorphous in the sense of these names as just defined; in other words, all morbid products have their normal analogues in the anatomical history of the organism including therein embryonic life. In accordance with this doctrine, now accepted by the most distinguished pathologists, the different morbid products are accounted for by either an abnormal multiplication of normal anatomical elements of the body (hypergenesis, hyperplasia), or by abnormal modifications of their development and growth, or by an error of situation.

Finally, a discovery with respect to tubercle, of great interest and importance, in 1865, was communicated to the French Academy of Medicine, by M. Villemin. By a series of experiments M. Villemin demonstrated that tuberculous disease may be communicated from man to certain inferior animals by inoculation. The animals selected by him for these experiments were rabbits and guinea-pigs. Portions of each of the tuberculous products having been inserted beneath the skin, and the animals destroyed after a period varying from two to three months, in the lungs especially, but also in other parts, tubercles were found in more or less abundance. These experiments have been repeated with the same result by many other observers.

The inoculability of tubercle does not prove that the disease may be communicated by means of the breath or by emanations from the body; yet, the fact affords ground for the suspicion that tuberculous patients may sometimes communicate the disease to those with whom they are for a long time in close intercourse, as, for example, in the case of husband and wife. Villemin claims that his experiments showing inoculability prove the existence of a virus in the tuberculous products; and that tuberculosis expresses a specific disease in the same sense as, for examples, glanders and syphilis are specific communicable diseases. On the other hand, experiments made by different observers appear to show that inoculation with pus as well as other non-tuberculous morbid products, and with septic matter of various kinds, gives rise to the same result as the inoculation with tubercle. This militates against the doctrine of a tuberculous virus. The production of gray tubercles in the lungs and other organs by the introduction into the blood of tuberculous and other matter, gives, as already stated, some support to the opinion that the gray tubercles may be due to auto-infection, being caused by the absorption of matter from degenerated morbid products of different kinds seated in the lungs or in other parts of the body.

Scrofula.

The term scrofula, as frequently used by medical practitioners and writers, has a comprehensive and an indefinite latitude of signification. In a restricted and definite sense it denotes an affection of the lymphatic glands, especially the superficial glands of the neck, occurring chiefly in children after the period of infancy, characterized by a morbid product which, if not truly tuberculous, bears a close resemblance to tubercle as regards its behavior and the morbid processes incident to it. The scrofulous product occasions more or less enlargement of the affected glands. It remains for an indefinite period apparently in a quiescent state, and it may be removed by absorption. If not absorbed, softening takes place, with but little evidence of inflammation; ulceration of the integument ensues, and the liquefied product is discharged. Finally, after a variable period, there is cicatrization resulting in an irregular, puckered, characteristic scar. The same series of events may occur in the bronchial glands, giving rise to what has been called *bronchial phthisis*. Clinical observation appears to show that they who suffer from a scrofulous affection of the glands of the neck in early life are not more liable than others to pulmonary tuberculosis in after-years.

According to the views of Virchow, Niemeyer, and others, the scrofulous enlargement of the lymphatic glands is due to a morbid increase of anatomical elements which these bodies contain in health, the process being a hyperplasia or morbid growth, to which inflammation is consecutive; and this product, like tubercle and other products, undergoes the cheesy metamorphosis. Cretefaction also may occur, as in the tuberculous product.

The absorption of the scrofulous product after it has undergone the cheesy metamorphosis, is by some supposed to be a cause of the development of tubercles in the lungs and other organs. The frequent existence of scrofula, however, without the occurrence of tuberculous disease in other situations, militates against, if it does not disprove, this supposition.

The existence of a constitutional state in children, called the scrofulous habit or diathesis, is generally recognized by practitioners and writers as manifested in affections occurring either with or without the affection of the glands, which has just been noticed. Enlargement of the head, tumefaction of the upper lip, or of the nose, swelling of the abdomen, and flaccidity of the muscles, are supposed to denote constitutional scrofula. Various affections are considered as local expressions of this diathesis, or, at least, as deriving from it important modifications. These affections are, certain of the cutaneous diseases, namely, eczema, impetigo, and lupus, especially when seated on the head or face; chronic coryza, otorrhœa, conjunctivitis, and superficial ulceration of the cornea; chronic suppurative inflammation of the joints, formerly known as white swellings; caries and necrosis of bones; bronchitis, and chronic inflammation of the intestinal mucous membrane. That these affections involve a morbid constitutional state, either congenital or acquired, is undoubtedly true; but that they originate in a special cachexia is by no means certain. Even in children who have a scrofulous affection of the glands, the concurrence may be accidental. It is certain that the various affections just named are often observed in cases in which the glands are not affected; and, *per contra*, the glands are often the seat of scrofula without the coexistence of any of the other so-called scrofulous affections.

Carcinoma.

In connection with the anatomical changes due to morbid products, may be noticed *carcinoma* or *cancer*. I shall pass by this product with a cursory notice. It is by no means unimportant. On the contrary, its importance and extent are such that it occupies a large space in pathology. and treatises are devoted specially to it. It will be found to give rise to a considerable number of individual diseases hereafter to be considered. But in a large proportion of cases the affection is seated either externally or in parts which are accessible, and the propriety of removal by the knife frequently becomes a question. Hence, it belongs to surgical rather than medical pathology, and is treated of at length in surgical works. For these reasons I shall devote to it but a few words. In most cases the carcinomatous product becomes the seat of more or less development into tumors which sometimes attain to a great size.

The terms carcinoma and cancer have been used heretofore with much looseness, having been applied to morbid growths differing from each other in essential points. In their present restricted scope of application, they embrace different forms or varieties which differ widely in appearances, but have in common certain characters which are distinctive. The general characteristics of the carcinomatous product, as regards its behavior during life, are as follows: It is a morbid development or growth which may go on indefinitely, giving rise to a tumor of greater or less size. It involves more or less destruction of the surrounding structures, partly by interfering with their nutrition, and in part by the inflammation which it excites. Sooner or later, if life be sufficiently prolonged, it leads to ulceration which becomes more or less extensive, eventuating in what is commonly called open cancer, and hemorrhage is apt to occur. The lymphatic glands in the neighborhood are secondarily affected in consequence, as generally supposed, of the transportation of morbid material to them by the lymphatics. Progressive destruction of parts and death therefrom (the product frequently occurring successively or simultaneously in different situations) is the rule to which there are few exceptions. Recovery is, however, possible, and it takes place by retrogressive processes which may involve either fatty or calcareous degeneration. As belonging to this general sketch, is to be added the liability to return, when situated in an accessible part and removed by the surgeon, either in the same part or in some new situation. In view of the salient points in its history just stated, the propriety of calling cancer a malignant disease is sufficiently apparent.

Anatomically considered, the different forms of cancer present notable points of difference. Three well-marked forms are generally recognized, viz., scirrhus or hard cancer, medullary or encephaloid, and colloid or alveolar, the two latter forms being distinguished from the first form as soft cancers. Each of these forms consists, in part, of a fibroid structure which is especially abundant in scirrhus, giving to this form its cartilage-like hardness. This structure is far less abundant in the two other forms. In medullary or encephaloid cancer the morbid growth bears a resemblance in its appearance to brain substance, as the names imply. In the colloid form, the fibroid structure is disposed in such a manner as to leave small spaces called areolæ or loculi, which are filled with a substance resembling glue. These forms are subdivided into numerous varieties which need not be noticed in this general account. The three forms, in addition to the fibroid tissue, or stroma, contain characteristic cell formations, or cancer cells. These are found on subjecting to microscopical examination scrapings from the cut surfaces of cancerous tumors, or the milky liquid

known as the cancer juice, which exudes when these tumors are incised. The presence of this juice is a distinctive character of cancer. There has been much discussion of late years respecting the existence of cells specially distinctive of cancer, and their reliability as a diagnostic criterion of cancerous growths. Without entering into the discussion, it may be stated that most microscopical observers, appear to believe in the existence of cells having characters distinctive of cancer, and that they are present in at least a large majority of specimens which are truly cancerous. The cells present a great variety of appearance, being round, caudated, fusiform, etc., and also varying largely in size. A cancer-cell is distinguished especially by the presence of a nucleus, or of nuclei, of large size, and by a large nucleolus. The nucleus, which varies in size, according to Bennett may occupy one-sixth to four-fifths of the volume of the cell. Frequently a cell contains more than a single nucleus, often two, and sometimes several nuclei; in the latter case it is sometimes called a mother cell. Acetic acid acts upon the cell-wall, rendering it transparent and sometimes dissolving it, while the nucleus is not affected. In some specimens the cells are few or wanting, but free nuclei exist in greater or less abundance. Whenever cells or free nuclei having the distinctive characters just stated are found, we are warranted in regarding them as evidence of the cancerous nature of the specimen, but it may be a question whether their absence constitutes negative proof sufficient to declare in all cases the non-existence of cancer. It is to be borne in mind that the minute quantity of matter which is placed under the field of the microscope may not contain cancer-cells in consequence of their being sparsely distributed throughout the morbid mass. They are not to be pronounced absent until several portions of the mass have been examined. Cancerous formations have been considered as pre-eminently heterologous or heteromorphous productions. But if we accept the views of Robin, Virchow, and other pathologists, even cancer-cells do not exemplify a principle of the generation of new anatomical elements in disease. They regard these cells as resulting from a deformation of epithelium or other normal anatomical elements which, at the same time, are multiplied to a greater or less extent. Robin points out differences as regards the appearance of cancer-cells corresponding to differences of the structure in which the carcinomatous exudation takes place.

Cancerous products are distinguished as *primary* and *secondary*. The first product which occurs is called primary, and products which subsequently take place are called secondary. It is generally supposed that secondary cancers are dependent on the primary, the latter furnishing germs which gain admission into the circulation, and, being deposited in other situations, become the point of departure for fresh manifestations of the disease. It has been already stated that, not only are the structures in immediate proximity to the deposit involved and destroyed, but the affection extends to the neighboring lymphatic glands. It may, however, be doubted whether secondary cancers more or less remote from the site of the primary cancer proceed from the latter; in other words, it is by no means certain that the system becomes infected by the introduction into the circulation of matter derived from an existing cancerous affection. Various facts go to show that a primary cancer involves an antecedent or underlying unknown special pathological condition called a cachexia. A predisposition to this disease, or the cancerous diathesis, is undoubtedly in some cases inherent in the system from birth, and inherited. Now, it is perhaps more probable that secondary cancers are dependent on the general or constitutional condition which led to the primary affection, than that

they proceed from an infection by the latter. This view is consistent with a fact which clinical experience appears to teach, viz., that secondary cancers are more apt to occur after the extirpation of a part primarily affected, than if surgical interference had not been resorted to. It is, however, proper to state that many, if not most, pathologists consider cancers as diffused by a cancerous infection derived from the part or parts primarily affected.

As regards the situation of cancers, there is a preference (so to speak) for certain organs. Rokitansky gives the following list of parts which are liable to be the seat of this disease in the order of their enumeration. "First, the uterus, the female breast, the stomach, the large intestine, and especially the rectum; next comes the cancer of lymphatic glands, especially as retro-peritoneal cancer accumulation in front of the vertebral column; hepatic peritoneal cancer; bone-cancer; cancer of the skin, and of the lips; of the brain; of the globe of the eye; of the testis; of the ovary; of the kidneys; of the tongue; of the œsophagus; of the salivary glands and the parotid."

In addition to the morbid products which have been noticed, namely, the fibrinous, the tuberculous, the scrofulous, and the carcinomatous, there are some which will be referred to in treating of individual diseases. One of these is the product which takes place in the Peyerian and solitary glands of the small intestine, and in the corresponding mesenteric glands, constituting the anatomical characteristic of typhoid fever. Morbid deposits, solid, or semi-solid, which are either substituted for, or penetrate by infiltration, the normal substance of parts, are embraced under the name *degenerations*. Other anatomical changes are distinguished by *morbid growths, or pathological new formations*. Degenerations and new formations will be briefly considered in the next chapter, together with transudations, or dropsies, changes caused by the abnormal presence of air or gases, called pneumatoses, and, finally, those dependent on animal and vegetable parasites.

CHAPTER III.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY— (Concluded.)

Lesions of Composition continued—Transudation—Dropsies—Fluxes—Degenerations—Fatty Degeneration—Fatty Growth—Calcareous Degeneration—Lardaceous or Waxy Degeneration—New Formations or Morbid Growths—Pneumatoses—Animal and Vegetable Parasites.

Transudations—Dropsies.

A MORBID condition affecting the composition of parts, consists in an abnormal accumulation of liquid, exterior to the vessels, derived from the blood. A liquid which escapes through the coats of vessels, which is devoid of coagulated fibrin or lymph, but holding in solution more or less of the constituents of the serum of the blood, is distinguished as a *transudation*. Transudations preserve the liquid state, in this respect differing from exudations, the latter being solid or semi-solid. The act of transu-

dation is physical, that is, it has no special relation to the vital endowments of the tissues, but only to their physical properties. The serous or watery portion of the blood percolates the walls of the vessels as any liquid confined in artificial tubes of leather or some porous material may transude. Transudations may not even involve the principle of *exosmosis*, which is operative to a considerable extent in living organisms. They take place as a result either of a morbid attenuation of the blood-serum, or of undue hydraulic pressure, or of both these physical causes combined; other circumstances, also, may co-operate by rendering the sides of the vessels more permeable. In a true transudation, however, there is no solution of continuity or rupture. Hemorrhage, therefore, is not a transudation unless it be admitted that the blood-corpuscles can pass through the pores of the vessels without the molecular coherence of the tissues being disturbed. Bloody serum, or serum colored with hæmatin, may transude, constituting what is called false hemorrhage.

Transudations may take place in different situations. Occurring in situations from which the liquids cannot escape, viz., within serous cavities and into the areolar tissue, they constitute *dropsies*. Occurring upon some internal surface whence the liquid is conveyed out of the body through an outlet, or, in other words, upon a mucous surface, they constitute *fluxes*. The latter do not now especially concern us, since they do not occasion lesions affecting the composition of parts. The transudations which constitute dropsies are alone to be considered in this connection.

The distinctive feature of a dropsy is, that the liquid which escapes through the coats of the vessels is not *liquor sanguinis*, but water containing more or less of the constituents of blood-serum. When liquor sanguinis or blood-plasma escapes, the results are coagulated fibrin or lymph, and certain metamorphoses or developments which were noticed in the preceding chapter. Blood-constituents which assume a solid or semi-solid form after leaving the vessels and become the seat of adventitious tissues, or of leucocytes, are exudations. On the other hand, liquid effusions devoid of coagulating material, undergoing no metamorphosis, not giving rise to new formations, in other words, in no sense blastemata or cytoblastemata, are transudations, and, if retained, such effusions constitute dropsies. It is proper to remark that this distinction is not always observed. Vogel, for example, applies the term "fibrinous dropsies" to accumulations of liquid which contain coagulated fibrin in greater or less abundance. According to the distinction just made, these are not correctly called dropsies; they are exudations, involving generally, if not always, inflammation. A true dropsy is not an effect of inflammation. Inflammation of serous membranes, it is true, frequently gives rise to more or less liquid effusion. But the effused liquid is turbid from the admixture of lymph, and contains more or less solid fibrin. In a dropsical accumulation, on the other hand, the liquid is generally clear, like the serum of the blood, and no solid fibrin or lymph is apparent. Again, while inflammatory effusion is due to a morbid condition (inflammation) of the serous membrane, in pure dropsy the morbid condition, on which the transudation depends, is situated elsewhere, the membrane itself being free from disease. Individual diseases exemplifying this contrast between inflammatory and dropsical effusions are pleuritis and hydrothorax, peritonitis and hydroperitoneum, true hydrocephalus and meningitis. The prefix *hydro* expresses the fact that the disease is dropsy.

In pure dropsy the effused liquid bears a resemblance, more or less close, to the serum of the blood. But it differs in different cases, owing to variations as regards the ingredients held in solution. It has usually

an alkaline reaction. It generally contains albumen in greater or less quantity. According to Lehmann, transudations into the pleural sac are richer in albumen than those into the peritoneal; there is still less albumen in dropsy of the arachnoid than in hydro-peritoneum, and effusions into the areolar tissue are the poorest in this constituent. When albumen is abundant, the liquid is viscid, and it may become so from the absorption of water. Dropsical effusions are sometimes red, from the presence of blood-pigment or hæmatin. Occasionally they are yellow or greenish, from the presence of bile-pigment. Fatty matter may be present in sufficient quantity to render the liquid opalescent or milky. Several of the saline ingredients of blood-serum are present, the chloride of sodium preponderating. Urea is occasionally found.

Dropsies receive different names according to their situation. Seated in the serous cavities, they are designated by prefixing *hydro* to the name of the membrane, as already stated. Dropsy of the areolar tissue of a part is called *œdema*. This name is applied to effusions into the areolar tissue of internal organs as well as beneath the integument. An effusion into the pulmonary air-cells is called œdema of the lungs. When subcutaneous œdema is general, that is, extending over the body, it receives the name *anasarca*.

Dropsy is always dependent on some antecedent morbid condition. It is never a primary affection. It is, in fact, not a disease *per se*, but only a symptom of disease. It is produced by the affections which stand in a causative relation to it, in two ways: 1st, by increased pressure from an accumulation of blood in the veins; and, 2d, by diminishing the density of the blood-serum. These two physical conditions comprise the mechanism of dropsical transudations. In all instances either there is an increase of hydraulic pressure in the veins from obstruction, or the blood is abnormally aqueous; and both these physical conditions may be combined. Dropsies seated in serous cavities may perhaps involve something more than simple transudation; that is, the effusion may not be purely a physical act. The small amount of liquid which serous cavities contain in health is not derived from the blood by transudation; for, inasmuch as the liquid differs in the different cavities, but is uniform in each cavity, there must be election and new combination of principles derived from the blood. Hence, the serous effusions in health are properly secretions; and it is probable that, in certain cases of dropsy, in addition to mechanical causes, there is hyper-secretion.[1]

The terms *general* and *local* dropsy express an important distinction. In general dropsy, subcutaneous œdema is diffused to a greater or less extent; that is, anasarca exists, together with more or less effusion into certain of the serous cavities, the peritoneal and pleural especially. The œdema appears first either in the lower extremities, or on the face, or simultaneously in both these situations, and thence extends over the body. The anasarca may be accompanied with a small or a considerable accumulation in the serous cavities. Now, all cases of general dropsy involve either an obstruction seated at or near the central organ of the circulation, or a morbid condition of the blood, or both may be combined. General dropsy, due to obstruction, is usually a symptom of disease of the heart; occurring in this connection, it is distinguished as *cardiac dropsy*. The dropsy, under these circumstances, is generally associated with difficulty of breathing (dyspnœa) out of proportion to the amount of effusion into the pleural cavities; also, with disturbed action of the heart, and more or less conges-

[1] *Vide* Robin, Sur les Humeurs, Paris, 1867.

tion of the surface, giving to the skin frequently a dusky hue. On the other hand, general dropsy due to a morbid condition of the blood, in the majority of cases, is connected with those affections of the kidneys embraced under the name Bright's disease. Occurring in this connection, it is called *renal dropsy*. Cases of this variety of dropsy are characterized by the presence of albumen in the urine (albuminuria), by pallor of the surface, and, as a rule, a less amount of dyspnœa than in cardiac dropsy. Irrespective of disease of the kidneys, or albuminuria, the blood sometimes becomes attenuated so as to give rise to general dropsy. It is occasionally incidental to protracted intermittents. I have known anasarca to a great degree, with effusion into the cavities, to occur in connection with anæmia due to lactation, without either renal or cardiac disease.

In local dropsy the effusion is limited chiefly to one serous cavity, or, if in the areolar tissue, it is confined to one organ or to a part of the body. The most frequent of local dropsies is hydro-peritoneum, which is dependent on obstruction of the vena portæ, generally as a result of hepatic disease, more especially the affection called cirrhosis. This, with other local dropsies, will be considered in connection with individual diseases; œdema of internal parts, when restricted to any organ or to a limited space, is due to hyperæmia or congestion which may occur under different circumstances. It may depend on venous obstruction, as when œdema of the lungs is produced by cardiac lesions which involve mitral obstruction. It is incidental to inflammation. The swelling in the neighborhood of an inflamed spot on the surface of the body is due to serous infiltration. This occurrence is generally of little moment, but it becomes an event of very grave importance when œdema of the glottis is incidental to pharyngitis. Œdema of the lungs is incidental to the congestion distinguished as *hypostatic*, due to gravitation of blood to the dependent parts from impairment of the forces carrrying on the circulation; it occurs in the last stage of fevers or other diseases characterized by *adynamia* or great depression of the powers of life.

Transudations upon mucous surfaces, constituting fluxes, will be considered as entering into certain individual diseases, in the second part of this work.

Degenerations—Fatty Degeneration.

The lesions of composition which have been considered do not involve, primarily, alterations of structure, or textural changes. Certain of the products noticed under the head of Exudations, it is true, lead to the destruction of the tissues surrounding them. This occurs in the progress of cancer and tubercle, but the destructive effects of these products are due to pressure, to disrupture from their accumulation, and to the inflammation which they excite. In transudations the structures remain unaffected except that they may become attenuated from the distension occasioned by the liquid. But the lesions now to be noticed are characterized by the substitution of morbid deposits for the normal substance of the affected parts, or by changes in composition arising from morbid infiltrations in the cells or tissues. These are the distinctive features of the lesions of composition which are commonly known as *degenerations*. And of these lesions, one of frequent occurrence, is the substitution of fat for the normal substance of tissues, or *fatty degeneration*. In the elucidation of this lesion and of other degenerative changes, the microscope, within late years, has rendered valuable service to pathology.

Different structures in various situations are found to present, in the

place of the substance peculiar to their normal composition, fatty granules or oil-drops. Muscles are especially prone to this change. It is often observed in the muscular walls of the heart. Examined with the microscope, the characters of the muscular fibre are more or less impaired or lost, and those of fatty matter are present. In proportion as this change has taken place, the tissue becomes softened, rupture is liable to occur, and, instead of the healthy color, the affected parts present a yellowish or tawny appearance. Of course, also, in proportion as the muscular substance is replaced by fat, the function proper to the structure is impaired; its power of contraction is diminished, and the affected organ is enfeebled.

An important distinction is between fatty growth and fatty degeneration. In fatty growth the adipose tissue is increased. This may take place beneath the integument and in any part of the body containing more or less of this tissue. Increased generally throughout the body beyond a certain extent, the condition known as obesity or corpulency is produced. This may take place in a degree to constitute a disease. On the other hand, a decrease of the amount of adipose tissue which belongs to health occurs in emaciation produced by a deficiency of the alimentary supplies which contribute to fatty growth, and by various diseases. In obesity or corpulence there is, in fact, hypertrophy or abnormal growth of the adipose tissue, and in emaciation there is atrophy of this tissue.

Fatty growth may be limited to a particular organ. Thus, taking the heart for an illustration, this organ in health presents a certain amount of adipose tissue. Hypertrophy of this tissue, or, in other words, increase of the fat vesicles, may occur to such an extent that the whole surface of the organ is covered with a thick layer of fat; the fat vesicles may also penetrate, in greater or less quantity, between the muscular fibres. Nevertheless, the muscular structure of the organ may remain unchanged. The heart is affected with obesity; but this is not fatty degeneration. In fatty degeneration the fatty matter occupies the place of muscular substance; that is, fat is contained within the sarcolemma at the expense of the normal contents or the musculine.

Fatty degeneration of voluntary muscles occurs as a result of protracted disuse. In cases of complete paralysis, after the function of the muscles has been suspended for a long time, fatty granules are found to have taken the place of the muscular substance. The same is true of the nerves involved in paralyzed parts. These structures become, in fact, disorganized in so far as fatty degeneration has taken place, and, in proportion to the amount of this change, their ability to resume their functions is impaired. This fact is of great importance in its bearing on the treatment of paralysis. A notable interruption of the circulation of blood within a part occasions defect in nutrition, and, as a consequence of the latter, it may lead to decomposing changes which are embraced under the name fatty or granulo-fatty degeneration. An example of this is the softening of a portion of the brain-substance as a result of the occlusion of an arterial branch by a fibrinous plug brought from the heart, or by the coagulation of fibrin at the point of the obstruction. The same may occur in other situations.

Fatty degeneration of the coats of the arteries, especially of the minute cerebral arteries, not unfrequently occurs in aged persons and in middle life. This fact, ascertained within late years by the aid of the microscope, has explained the occurrence of apoplectic extravasation of blood in a large proportion of cases. The cohesion and resistance of the arterial coats being diminished by the displacement of their proper substance by fatty granules, they are liable to rupture; hence the occurrence of hemorrhage into the brain, giving rise to apoplexy and hemiplegia.

Fatty matter is apt to be deposited, in abnormal quantity, within the secreting cells of important glands. Accumulating unduly within the hepatic cells, fatty liver is produced; and, in like manner, fatty kidney, one of the forms of Bright's disease, is produced by the deposit of fat within the cells of the convoluted tubes. So, also, the epithelium lining the gastro-intestinal tubules and in other situations may be the seat of fatty degeneration.

Morbid exudations undergo changes which belong in this category. This is true of the exudation of fibrin, of the morbid products embraced under the name tubercle, and of the scrofulous product. As already stated, a mode in which it is possible for cancer to undergo retrogression and cure is by a fatty degeneration.

An interesting example of fatty degeneration is afforded by the cornea in some persons advancing toward old age. The outer margin of the cornea presents a pale, opaque ring, varying in width and extent, which is familiar to every observer as the *arcus senilis*. It has been ascertained that this is due to the presence of fat. Canton, of London, who was the first to attribute the arcus senilis to fatty degeneration, considered it as uniformly associated with a similar condition affecting internal parts, and more especially the heart. Hence, he regarded it as possessing much diagnostic value. Clinical observation does not show it to be reliable evidence of the coexistence of fatty degeneration of the heart or other internal parts, nor, when associated with the latter, is it a criterion of the amount of degeneration, as claimed by Canton; but taken in connection with other circumstances, it possesses a certain amount of diagnostic significance.

A variety of fatty degeneration, affecting especially the larger arteries and the valves of the heart, is called *atheroma*, a term signifying pap or pulp. This variety is highly important as leading to certain grave accidents and lesions pertaining to the parts affected. The affection consists, primarily, of a deposit beneath the lining membrane of the arteries, or the endocardium investing the valves of the heart, of a substance which presents a yellowish or whitish color, and is of a cheesy consistence. Examined microscopically, this substance is found to be composed of fatty granules, with crystals of cholesterin in abundance, and certain earthy ingredients. The accumulation of this deposit causes atrophy of the structure in contact with it, and may lead to softening and separation of the delicate membrane beneath which it is situated. In this way the parts are weakened, and hence occurs, in the arteries, especially the aorta and the large vessels connected with it, aneurismal dilatation. Situated in the valves of the heart, it may result in rupture, involving serious valvular lesions. It is apt to precede the deposit of calcareous matter in abundance, both in the arteries and within the heart, leading, in the latter, to what has been called ossification of the valves.

The importance of fatty degeneration, as regards its pathological effects, of course depends on the parts affected, together with and extent of the disorganization. In most situations the change of structure is irrecoverable.

Calcareous Degeneration.

A change in composition, due to an infiltration of earthy salts, in more or less abundance—the phosphate of lime and magnesia, and the carbonate of lime—constitutes what is called the *calcareous degeneration*, *calcification*, or *cretefaction*. As just stated, this is apt to supervene upon the atheromatous deposit in the large arteries and within the heart, leading,

in the latter situation, to various deformations of the valves. The term ossification is, in general, incorrectly applied to this change. Virchow prefers the name *petrification*. The calcareous deposit does not present the structure peculiar to bone, but consists of the earthy salts just named, without any structural arrangement. True bony structure, however, is sometimes produced in situations in which it does not exist normally. Thus produced it is called an *osteophyte*. The smaller arteries not unfrequently become calcified, especially in advanced life, giving rise, in some cases, to serious consequences. The gangrene of the feet and legs, which is peculiar to old persons, called *gangræna senilis*, is attributable, in certain cases at least, to obstruction of the circulation from calcareous degeneration of the distributing arteries of the lower extremities. The arteries of the brain, becoming calcareous and consequently brittle, sometimes give way, and this is the source of the hemorrhage in certain cases of apoplexy and hemiplegia. The obstruction of the circulation due to calcification of the cerebral arteries, may be sufficient to give rise to non-inflammatory softening of the brain, by diminishing the amount of supplies requisite for healthy nutrition. By roughening the inner surfaces of the vessels it may occasion coagulation of the fibrin of the blood, or thrombosis.

Aside from the structures which have been mentioned, various others may be the seat of calcareous deposit. Not unfrequently the serous membranes present plates of bony-like substances, more or less numerous and large. I have met with a case of old pleuritis, in which the pleura had become hardened by calcareous deposit to such an extent that it was removed entire, together with several quarts of liquid which it contained, and, when open, and the liquid removed, it did not collapse, but retained the form of a solid box. Exudations and morbid growths may undergo the calcareous degeneration. This occurs in simple fibrinous exudation, in cancer and in tubercle. Ths pulmonary calculi, or obsolete tubercles, are masses of earthy salts which have taken the place of miliary tubercles.

Lardaceous or Waxy Degeneration.

Another change in composition has received several names, to wit, the *lardaceous*, *waxy*, *albuminoid*, and *amyloid* degeneration. The distinctive feature of this degenerative change consists in an infiltration by a morbid material, the nature of which is not yet satisfactorily ascertained. This material first appears in the walls of the small vessels, and thence pervades the adjacent structures. Affected parts are increased in volume and weight; there is also a notable increase of firmness or stiffness; the surfaces on section present a dull, translucent appearance, resembling fat bacon and wax, and hence, the significance of the terms lardaceous and waxy.

Wagner[1] found this lesion in 48 of 1200 autopsies. The organs which are most apt to be affected are the liver, the kidneys, the spleen, and the lymphatic glands; but it may be seated in any of the soft parts of the body. The names albuminoid and amyloid imply different views as to the nature of the infiltration. It is generally considered to be an albuminoid product, that is, resembling albumen. Virchow was led to suppose that it is a substance analogous to starch, or to cellulose, as expressed by the name amyloid. The evidence relied upon for the latter supposition consists in the change of color produced by iodine. If a little sulphuric acid be first cautiously added, the application of iodine is followed by

[1] Archiv. der Heilkunde, 1861.

either a blue or violet color. The iodine test is generally considered insufficient as evidence of the amyloid character of the substance, and very few at the present time accept the conclusion of Virchow. Iodine, without the previous application of sulphuric acid, however, is a test of the anatomical change under consideration: applied to healthy parts it gives a yellow tinge, whereas, a dark-brown color is produced if this change exist. With the present uncertainty respecting the nature of the material, the names lardaceous or waxy, which relate to the peculiar appearance of the affected parts, are to be preferred.

The lardaceous or waxy degeneration produces injury, in proportion to its amount, by deforming cells, encumbering tissues, and diminishing the calibre of the smaller arteries. The deposit does not undergo softening. Its presence does not appear to excite inflammation. It is doubtful if it be ever absorbed. The change is followed by serious consequences according to the parts affected, together with the degree and extent of the infiltration. It leads to evil results by obstructing the circulation in, and compromising the functions of, the parts affected. For example, in the kidneys, the elimination of urea is interfered with, and, if the infiltration be great, uræmia may be the result. In like manner, if the liver be affected, the functions of this organ are impaired in proportion to the amount of infiltration. Affecting thus an important organ, the lesion is of a grave character, more especially if it be permanent. According to Dr. Wilks, who analyzed nine cases occurring under his own observation, the lardaceous or waxy infiltration implies a long standing and deep cachexia, which is seen in its most intense form after protracted caries and necrosis of bone, having its origin in tuberculosis or syphilis. In the great mass of cases it is associated with disease of bone, syphilis, or scrofula. Of sixty-six cases analyzed by Dickinson, fifty-one were associated with a profuse and long-continued drain of pus. It seems, in some cases, attributable to the malarial cachexia.

Interesting and important changes in the composition of parts are caused by the deposit within them of pigment derived from the blood. In general, the coloring matter in *pigmentation*, as it is called, is altered hematin from the blood-globules. An exception is the bile pigment; although this is hardly exceptional if it be true that the biliverdin is a product of the destruction of the blood-globules. Pigmentation will be referred to in connection with the morbid condition of the blood known as melanæmia, and, in the second part of this work, in connection with malarial fevers, Addison's disease, diseases of the lungs, and jaundice.

New Formations or Morbid Growths.

Changes in composition, of great practical importance, proceed, evidently, from *new formations*, *neoplasms*, *or morbid growths*. Some of the morbid products already considered properly belong in this category, namely, gray tubercle and carcinoma; but, for the most part, the new formations or morbid growths now referred to are embraced under the head of tumors. They belong to surgical rather than medical pathology, inasmuch as they are often situated either externally or where they are accessible to manual examination, and may be removed with the knife or are treated with the appliances of surgery. This division of anatomical changes I shall therefore pass by, with scarcely more than a simple allusion to it, referring the reader to surgical treatises or to works devoted to morbid anatomy. Morbid growths have been heretofore considered by

pathologists as consisting of *analogous* and *non-analogous* structures; the first being morbid structures, either identical with, or analogous to those found in the healthy body, that is, normal, and the second being structures essentially abnormal, in other words having no analogues among the healthy tissues of the body. As expressive of this distinction, the terms omologous or omorphous, and heterologous or heteromorphous, have been applied to morbid growths, as well as to morbid exudations. There is probably no just ground for this distinction. The so-called new formations are either normal structures abnormally situated, or the normal anatomical elements of a part developed and multiplied to such an extent as to constitute morbid growths or tumors. Virchow uses the term homologous or homœoplastic, as applied to morbid growths, to denote those, the structure of which is identical with that of the parts in which they are developed; and he uses the term heterologous or heteroplastic to denote growths differing in structure from the parts in which they are seated. Examples of the latter are epithelial tumors in the walls of the heart, tumors of cerebral substance in the ovaries, cartilaginous growths in different situations, etc. The term *Heterotopia* is used to denote productions normal in character, but abnormal in situation. The division by Robin of the anatomical components of the body into *fundamental* and *accessory* elements renders intelligible the production of many morbid growths or tumors. The fundamental elements are those which are endowed with known functions, and which make up the greater portion of the body, viz., the muscular, nervous, osseous, glandular, etc., structures. The accessory elements are certain superadded constituents, the purposes of which are often not apparent. Among the accessory anatomical elements are various cellular or corpuscular bodies. Examples of the latter are the *embryoplastic* cells and nuclei of Robin, called also *fibroplastic;* cells found in the mucous tissue, the skin, serous membranes, and the lungs, called by Robin *cytoblastions; myeolocytes*, or cells found in the substance of the brain, the spinal cord, and in one of the beds of the retina; *medulla cells*, and *myeoloplaxes*, cells in the marrow of bones, etc. Now, these accessory elements are liable to be multiplied to a greater or less extent, and they are found to form the predominant and characteristic constituents of certain morbid growths or tumors. They do not grow, but they are multiplied; that is, the augmentation is of number, not of size. Hence, the proper designation of the process by which morbid growths and tumors are in this way produced is *hypergenesis*, or, after Virchow, *hyperplasia*. Thus, according to Robin, cytoblastions are found in abundance in certain mucous vegetations, in the gray semi-transparent granulations of the lungs, in the so-called tubercular or granular meningitis, in the affection of the eyelids called chalazion, and in syphilitic tubercles; myeolocytes constitute the anatomical characteristic of certain affections of the retina, and of certain tumors of the brain, often called erroneously cancerous; fibroplastic cells give a distinctive feature to various tumors often confounded with cancer; myeoloplaxes are the point of departure for osteo-sarcoma, etc. According to Virchow, new formations or neoplasms are, in general, due to an abnormal proliferation of cells belonging to the connective tissue.

The different classes of tumors are designated by names expressive of their anatomical composition and disposition, to which is added the suffix *oma* (ωμα). Examples are as follows: Fibroma, myxoma, lipoma, angioma, adenoma, cystoma, epithelioma, enchondroma, myoma, osteoma, carcinoma, neuroma, names denoting respectively fibrous, mucous, fatty,

vascular, cystic, glandular, epithelial, cartilaginous, muscular, osseous, cancerous, and nervous tumors.

Pneumatoses.

In connection with morbid changes in the composition of parts, may be appropriately noticed those which depend on the presence of either air or gas in abnormal situations, and their abnormal amount in places in which they exist to a certain extent in health. Morbid conditions of this kind are collectively called *pneumatoses*. Air or gas diffused within the meshes of the areolar or connective tissue constitutes the morbid condition known as *emphysema*. This term is also applied to the over-accumulation of air in the air-vesicles or cells in connection with their dilatation, constituting an affection called pulmonary or vesicular emphysema, which will be hereafter considered. Extravasation of air into the areolar or connective tissue which unites together the lobules of the lungs is distinguished as interlobular emphysema. The latter affection is due generally, if not always, to rupture of the air-tubes or cells. Subcutaneous emphysema extending more or less, and sometimes existing to such an extent as to increase enormously the volume of the body, is caused by rupture or a wound of the lungs or air passages, the movements of respiration forcing the air through the aperture, and diffusing it by means of the extensive relations of the areolar tissue. But gas may be generated within the areolar tissue of a part by putrefaction or other chemical changes. I have known emphysema of the leg to be produced in connection with suppuration and the formation of abscesses. This may occasionally occur in internal organs. In some cases of perforation of the intestine, the latter becoming adherent to the abdominal walls, diffuse cellulitis follows, and intestinal gas may be more or less diffused beneath the integument.

Air or gas may accumulate in serous cavities, either introduced from without in consequence of perforation, or generated within by chemical changes, or possibly by a process of secretion. Affections of serous membranes characterized by this feature are distinguished by the prefix *pneumo;* thus, pneumo-thorax, pneumo-pericardium, etc.

The different sections of the alimentary canal contain a variable quantity of gas in health. A morbid increase gives rise to *flatulency* and *tympanites*. The former term is applied when the evidence of a morbid amount of gas is afforded by its movements (borborygmus) and its expulsion either by the mouth or anus; the latter, when it is retained sufficiently to cause distension with augmented resonance of the abdomen on percussion. Generally the gas is generated by chemical changes in the contents of the canal; but it is difficult to account for its production always in this way, and, hence, it has been inferred that gas may be secreted from a mucous surface. The latter supposition seems to be necessary in order to account for the large amount of gas suddenly developed in cases of hysteria and other nervous affections. Air may be swallowed in large quantity, as it is by horses affected with the habit called wind-sucking or crib-biting.

Animal and Vegetable Parasites.

Finally, in this division of anatomical changes may be included animal and vegetable parasites. Here is a field in pathology which modern researches have shown to be extensive and highly interesting, but which must be passed by with a very cursory notice.

Microscopical examination of certain morbid products obtained from

the skin and mucuos surfaces shows vegetable structures belonging to the series of cryptogamia, or flowerless plants propagated by spores, and to the class called *Thallophytes*, which includes lichens, algæ, and fungi. Various species of algæ and fungi have been ascertained, some of which are characteristic, and thus constitute diagnostic criteria of certain forms of disease. I must content myself with a simple enumeration of the different species found first on the skin, and next on mucous surfaces. A species of fungus (*trichophyton tonsurans*) is found about the hair follicles in the affection of the scalp known as *herpes tonsurans*. Another species (*microsporon audouni*) exists, in the same situation, in the affection of the scalp which has been called *porrigo decalvans*, or *alopecia circumscripta*. Another species (*achorion Schœnleinii*) belongs to the disease, affecting especially the scalp, but sometimes other parts of the skin, called *favus*, or the true *tinea capitis*. Another species (*microsporon mentagrophytes*) characterizes *sycosis* or *mentagra*, a disease affecting those portions of the face and neck which are covered with hair. Another species (*microsporon furfur*) exists in that variety of squamous disease, affecting different portions of the skin, but especially over the chest and abdomen, called *pityriasis versicolor vel nigra*. The presence of the cryptogamic plant appears to constitute an essential pathological element in these several contagious affections, and they are probably communicated by means of the germinal bodies called spores. The treatment of these affections involves measures to effect the destruction of the parasitic vegetable.

On mucous surfaces the following species have been ascertained: In aphthæ or thrush (muguet) and in diptheria, a fungus (*oidium albicans*) affecting the mouth, œsophagus, intestines, and anus. The algous vegetable known as the yeast plant (*crytococcus cerevisiæ*) in the œsophagus, stomach, and intestines. Another species of alga (*merismopœdia ventriculi*), commonly know as the *sarcina ventriculi*, found in matters vomited, also in the fæces, and in gangrenous abscess of the lung. Another species (*Leptothrix buccalis*), found in coatings on the tongue and matter collecting between the teeth, a species of fungus found in the matter of expectoration in cases of tuberculosis described by Bennett.[1]

Animal parasites are divided into those inhabiting the exterior of the body, and those infesting internal parts. The former are called *epizoa* and the latter *entozoa*. Under the head of epizoa are included the insects which invade different portions of the surface and multiply in consequence of neglect and filth, without being associated with disease, viz., the flea, the head-louse, the body-louse, the crab-louse; together with certain animals which penetrate the skin and give rise to more or less local inflammation, such as the West India chigoe. In addition to these, the cutaneous disease known as scabies, or vulgarly called itch, is characterized by the presence of a parasite called the *acarus scabiei*, or itch animalcule. It is by means of the transference of these minute insects, or of their ova, that this disease is communicated from one person to another. Another animalcular parasite called the *acarus folliculorum* inhabits the hair follicles and sebaceous glands, especially on the face, in healthy persons.

The human entoza are numerous, and much important information has been obtained, within late years, respecting their production and development. For this, the reader must consult more comprehensive pathological

[1] The student desirous of studying the subject of vegetable parasites may consult Robin's treatise entitled *Histoire naturelle des végétaux parasites qui croissent sur l'homme et sur les animaux vivants*. The nomenclature of Robin has been followed in the above enumeration.

treatises, or works specially devoted to Helminthology. Suffice it to say that there are no longer grounds for maintaining the doctrine of equivocal generation, a doctrine which has heretofore been held by some. These parasites originate from either ova or animals which are introduced into the body from without, and which find in certain parts of the organism the conditions necessary for their development and growth. Certain of the entozoa are involved in individual diseases, and will be noticed hereafter in treating of the latter. In the following list of the more important of the entozoa of man, they are arranged in their proper zoölogical divisions. HELMINTHIA HEMATOIDEA, thread or round worms: *Filaria medinensis* or Guinea-worm, found in the areolar tissue; *filaria bronchialis*, in the bronchial glands; *filaria oculi*, in the crystalline lens; *Tricocephalus dispar*, in the cæcum; *spiroptera hominis*, in the urinary bladder; *strongylus gigas*, in the kidneys; *ascaris lumbricoides*, in the small intestine; *ascaris alata*, in the small intestine; *oxyuris vermicularis*, in the rectum; *anchylostoma duodenale*, in the duodenum; *trichina spiralis*, in the muscles. Of this division, the worms which are chiefly important in a practical view are the trichina spiralis, ascaris lumbricoides, or lumbricoid, and the oxyuris vermicularis, or vulgarly pin-worm. The others are comparatively unimportant to the practitioner, either on account of their infrequency, or from their giving rise to little or no inconvenience. TREMATODIA, or worms with organs for suction: *Distoma hepaticum*, in the biliary ducts; *distoma lanceolatum*, or liver fluke, in the same situation; *distoma oculi*, in the crystalline lens; *distoma hæmatobium*, in the vena portæ. CESTOIDEA, or *tapeworms*: *Botriocephalus latus*, or *tænia lata*, in the small intestine; *tænia solium*, in the same situation; *tænia nana*, in the same situation; *cysticercus cellulosus*, in any of the organs or tissues of the body; *echinococcus hominis*, in hydatid cysts found in the liver, ovaries, and other parts.

The trematoda or suction-worms are of rare occurrence in man, and comparatively unimportant. Those found in the bile-ducts are not uncommon in inferior animals. The intestinal cestoid or tapeworms are not very infrequent, and are of importance to the physician. They will be considered hereafter. The *cysticercus* and *echinococcus* are now shown to be essentially cestoid or tapeworms, which, from their situation within the solid structures of the body, fail to become developed; they are, in other words, immature tænia. The sacs or cysts, frequently of large size, which contain *echinococci* in greater or less number, are called *hydatids* or *acephalocysts*. The history of these, and of the cysticerci, although embracing points of much interest and practical importance, is not consistent with the scope of this work.

CHAPTER IV.

MORBID CONDITIONS OF THE BLOOD.

General Remarks—Classification of the Constituents of the Blood—Morbid Conditions relating to the Organized or Corpuscular Element—Plethora—Anæmia—Apnœa—Leucocythemia.

HAVING sketched in the preceding chapters the anatomical changes produced by disease in the solid parts of the body, morbid conditions of the fluids next claim attention. The fluids of the body, in health, consist of, *first*, the blood, and, *second*, various liquids separated or formed from the blood, constituting exhalations, secretions, and excretions. The latter class of fluids, viz., those derived from the blood, are liable to numerous morbid changes. These are often of intrinsic importance, and they form important events or symptoms in the history of different individual diseases. It will be sufficient to consider the morbid changes occurring in the exhaled, secreted, and excreted fluids, in connection with individual diseases in the second part of this work. But the morbid conditions of the blood are to be considered briefly by way of preparation for entering on the study of individual diseases.

As expressive of the importance of the blood, it is distinguished as the *vital* fluid. In literature and common parlance it represents life. "Life's blood" is a common expression. To have one's blood is to take life. The importance of the blood is shown by the fact that its presence in all the so-called vital organs is indispensable to the exercise of their functions. A striking and familiar illustration of this fact is afforded by the temporary loss of the mental faculties and consciousness as a result of a momentary arrest of the supply of blood to the brain in syncope or fainting. The blood, in fact, may be said to be the grand condition of vitality. Its detention from a part occasions the molecular death of the part, *i. e.*, gangrene or sphacelus. Its abstraction, beyond a certain limit, from the body occasions general or somatic death. The suspension of its distribution by an arrest of the heart's action for two or three minutes only is fatal. It forms a vital medium for all the organs essential to life, on which they are dependent, as the body or the blood itself is dependent on the surrounding atmosphere. The physiological relations of the blood to the solid parts being so intimate, it might reasonably be expected, *à priori*, that pathological changes in this fluid should give rise to corresponding morbid phenomena in the organs and tissues of the body. Observation shows this to be true. There are grounds for the belief that a large proportion of the morbid actions and changes which occur in the solid parts are due to prior alterations in the blood. In many instances, as will be hereafter seen, the dependence of the former on the latter may be inferred or rendered probable, although not demonstrable with our existing knowledge. Supplies for the growth and repair of the whole body are contained in the blood. This fluid, therefore, represents in its constituents all the elements which enter into the composition of all the solid parts. It is taking but a step from the prosaic walks of scientific fact to the domain of fancy to say that the blood is the solid body in a liquid state. "The blood is the centre round which the general metamorphosis of animal

matter revolves and in which it is perfected."[1] It might be rationally predicted that morbid alterations in its composition and distribution lead to diseases seated in the solids, and this will be found to be the case. Another aspect foreshadowing the importance of the blood in its pathological relations, is its office as a reservoir for the accumulation of effete principles, the detritus of the tissues, which are to be eliminated by excretion. Here is a source of disease, as will be presently seen. Again, the physiological activity, or mobility, of the blood is very great. In this respect it is in striking contrast to the solid parts. It is the seat of unceasing changes, and yet, in health, maintains a uniform state as regards its organization and composition. New matter derived from the ingesta is daily added in considerable quantity, and a proportionate amount is derived from the decomposition of the tissues. Portions are appropriated by the different structures. Other portions are secreted for various useful purposes in the economy. Other portions are thrown off or excreted. There is a constant interchange of gaseous elements with the surrounding atmosphere by means of respiration and through the cutaneous surface. Thus it is the seat of constant and great changes, denoting wonderful activity, and yet its constitution remains the same. In this fact are admirably exemplified the precision and adaptation of the laws presiding over the safety and welfare of the organism. But this activity necessarily renders it more liable to morbid actions and conditions than the solid parts which in health are less active and more stable.

The blood is a complex fluid. It contains a large number of ingredients, preserving, however, certain fixed anatomical characters. Anatomically considered, it consists of certain corpuscular bodies, viz., the red globules, the white globules or leucocytes, and globulins which are suspended in a liquid called the *liquor sanguinis*, *lympha sanguinis*, blood-plasma, or inter-cellular fluid. These are resolvable by analysis into numerous elements, some of which are organic, *i. e.*, peculiar to organized bodies, and others inorganic or mineral. Examples of the organic elements are fibrin, albumen, hæmatin, etc. The inorganic elements embrace various saline ingredients, iron, water, and several gases. Further details belong to anatomy and physiology. It is necessary thus to glance at the composition of the blood in order to arrange its morbid conditions. The morbid conditions relate to the different constituents of the blood, and, with a view to the consideration of pathological changes, these constituents may be distributed into three groups. The first group will embrace the corpuscular, distinguished also as the organized, constituents. The second group will consist of the organic elements. The third group will comprise the mineral substances. Morbid conditions affecting severally these three groups will be first considered in the foregoing order, and, afterward, morbid conditions due to the introduction into the blood of substances which do not enter into its normal composition. Even with our present imperfect knowledge of the blood in health and disease, it is, in itself, a large field of study, which, considered as a distinct province of medicine, is called *Hæmatology*.

Of the corpuscular or organized constituents of the blood, the most abundant and important are the *red globules*. The known morbid changes affecting these relate, in the first place, to their number. They may be morbidly increased or diminished in number. An increase of the number of red globules beyond the healthy limit constitutes the morbid condition called *plethora*. A diminution below the limit of health constitutes the morbid condition called *anæmia*.

[1] Lehmann.

Plethora.

The relative proportion of red globules to the other constituents of the blood may be increased by diminution of the latter. This obtains, in a marked degree, in epidemic cholera, owing to the draining away, through the intestinal canal, of the water of the blood, together with various elements held in solution by the transuded liquid. The density of the blood in this disease is notably increased; it becomes thick and heavy, and the circulation is mechanically impeded. Under these circumstances, the red globules are relatively in abnormal excess, although they are actually less in number than in health. The term plethora is only applicable to an actual increase of the number of the red globules. This is now the significance of the term, without regard to the quantity of the mass of blood. An increase of the mass, causing over-repletion of the vessels, does not constitute plethora, although implied in the etymology of the term. This condition is called *polyæmia*. Its existence to an extent sufficient to constitute a morbid condition of importance is doubtful.

The functions of the red globules in health are not fully understood. Their relative normal ratio to the other constituents of the blood differs considerably in different animals. They appear to sustain a certain relation to vigor, strength, and activity; that is, they are abundant in races, breeds, and individuals, in proportion as the general attributes of the body just named are marked. Their importance is shown by the fact that animals bled nearly to death may be reanimated by injecting into the veins red corpuscles suspended in serum, and not by the introduction of the other constituents of the blood without the red corpuscles. From what is known of their physiological relations, it might be inferred that the effects of their morbid excess would be over-activity of the circulation and undue excitation of organs in proportion to their normal activity and the quantity of blood which they receive in health. The phenomena of plethora denote these effects. The power of the heart's action is increased; the temperature of the body is raised; the brain is stimulated, giving rise to unusual mental energy and excitement. Sensibility and muscular irritability are augmented. In comparing, however, different persons, it is not easy to draw the line of demarcation between more or less intensity of the so-called sanguine temperament and plethora. A better idea of plethora, as a morbid condition, is formed by a comparison of the same person at different periods, and especially if the person have naturally a temperament not notably sanguine. He acquires more color in the prolabia and face; the mucous membranes are reddened; the pulse is full and strong; the heart's impulse is increased; the physical and mental powers are more active; the body is notably warm. Pain in the head is readily induced by stimulants or mental excitement, owing to the abnormal power of the circulation. This condition involves a liability to active cerebral congestion. It is supposed to constitute a predisposition to acute inflammations. It doubtless tends to render inflammations more intense, and to increase the symptomatic febrile movement. It may favor hemorrhages especially into the brain, by means of the increased force of the circulation. On the other hand, an abundance of red globules exempts from nervous disorders to which, as will presently be seen, a paucity of red globules predisposes.

The causes of plethora are, *first*, a constitutional tendency which may be congenital or inherited; *second*, over-feeding, with the use of generous wines and condiments; *third*, diminished expenditure of blood constituents in nutrition, incident to ease, idleness, and luxurious habits, the digestive and assimilative functions remaining active; and, *fourth*, the arrest of

periodical or habitual hemorrhages, or some other drain to which the system had become accustomed. These several causes are frequently combined.

It is important for the physician to appreciate the condition of plethora, in order to avert, by appropriate management, the evils to which it tends; and, as an incidental element in different diseases, it is to be taken into account in considering the effects of therapeutical measures. It is relieved, for the time, most promptly and efficiently by bloodletting. An immediate effect of the abstraction of blood is a notable reduction in quantity of the red globules. Of course, the propriety of resorting to bloodletting will depend on the degree of plethora and the apparent imminency of evil results. Other means to diminish the excess of red globules are, a reduced diet as regards the quantity and quality of food, and exercise in order to increase the expenditure of blood-elements in repairing muscular waste and to render the amount of eliminated matter more abundant. Certain medicines appear to exert a direct effect upon the number of red globules. Mercury is such a remedy, as shown by the pallor which accompanies salivation. Mercurialization, however, is never indicated for the attainment merely of this object.

It is important not to confound plethora with other morbid conditions of the blood or circulation. Fulness of the vessels, due to some impediment to the circulation, has not unfrequently been considered as plethora. This may exist when the red globules are diminished, rather than increased. A pseudo-plethora, for example, is not uncommon in pregnancy, the red globules being diminished, and the proportionate quantity of water being notably increased, in this state. Bleeding was formerly employed with reference to this pseudo-plethoric condition, of course with an injurious effect on the constitution of the blood. With pseudo-plethora, or fulness of the vessels, there is often evidence of deficient oxygenation of the blood, together with dulness and oppression, instead of heightened activity of the functions of the brain and other organs. True plethora is to be determined by the symptomatic phenomena which have been mentioned, taken in connection with the evidence afforded by the pulse, and other symptoms, of an unobstructed, free circulation, with the activity of the digestive and assimilative functions, and the existence of one or more of the conditions under which this morbid condition is known to be produced. A microscopical examination of the blood may suffice to determine the existence of plethora, if the observer be sufficiently practised to decide whether the red globules, in several successive specimens, are in excess or not. It may be determined by a quantitative analysis, but the process is too tedious and delicate for ordinary clinical purposes.

As regards the essential pathological nature of plethora, all that can be said is, it consists in a hypergenesis of the most important of the organized or corpuscular constituents of the blood, the red globules. The pathologist might expect to explain this morbid condition more fully, if the physiologist were able to tell us where and by what process the red globules are normally produced.

Anæmia.

A morbid diminution of the red globules of the blood constitutes *anæmia*. The etymology denotes diminution of the mass of blood, but conventionally, the term is used to signify reduction of the quantity of red globules. *Spanæmia* is sometimes used in the same sense. In this definition of anæmia the sense of the term is restricted to a morbid condition of the

blood. The term is also used to denote a deficiency of blood, and especially of arterial blood, in different organs. Thus, it is customary to say, anæmia of the brain, of the liver, etc. In this sense the term denotes a condition the opposite of hyperæmia or congestion. *Ischæmia* is a term used to denote a local anæmia. We are here to consider anæmia as a morbid condition of the blood.

The purest exemplification of anæmia is afforded by cases in which it has been produced by copious hemorrhages or repeated bloodlettings. It is not easy to effect, except for a transient period, a considerable reduction in the mass of blood. After a loss by hemorrhage or bloodletting, the quantity of liquid which has escaped is quickly replaced, but the red globules are not so speedily renewed, and, hence, the latter continue, for a greater or less period, to be deficient. This condition is one of the forms of so-called impoverished or poor blood. The degree of impoverishment varies. The proportion of red globules has been observed to fall below the normal range (120 to 130 in 1000 parts) to 70, 60, and even 21 to 1000 parts.

Anæmia is of frequent occurrence. It is incident to a variety of diseases. It gives rise to a multiplicity of morbid phenomena. It is a condition highly important for the physician to appreciate and recognize. The knowledge of this condition, obtained within late years, constitutes one of the most striking of the characteristics of modern medicine, in view of its importance in medical practice. The condition occurs much more frequently than its opposite, viz., plethora.

In general terms, the pathological effects of anæmia are the reverse of those due to plethora. The power of the circulation is diminished, and there is a deficiency of the functional energy of different organs; the latter is more marked in different organs according to the quantity of blood which they receive in health. The phenomena denote these effects. The temperature is lessened. Anæmic patients have coolness of the surface, and especially cold extremities. They are not so able to resist cold as the plethoric. The action of the heart is feeble; the pulse is small, weak, compressible. The action of the heart is easily disturbed, becoming rapid from slight causes, and frequently irregular. The mental energy is diminished; persons are not adequate to the intellectual efforts of which they are capable in health. The strength of will and determination of purpose are impaired. The vital functions are languidly performed. The muscular strength is diminished; fatigue follows moderate or slight exercise. The surface is generally pallid from the deficiency of the hæmatin or coloring matter contained in the red globules. This pallor is apparent in the face, and especially the prolabia. The mucous membranes accessible to view have less redness than in health. The countenance may at once denote the existence of anæmia if the condition be marked. It is, however, important to state that in some persons who have an unusual vascularity of the face, anæmia may exist, as determined by physical signs and the pathological effects, not only without notable pallor, but even with a rosy complexion. In some cases pallor of the prolabia is noticeable in the morning, or when the patient is fatigued, disappearing under excitement. The urine frequently has a low specific gravity, owing to a deficiency of urea; and it is often notably limpid from a deficiency of pigment, a fact which may be cited as going to show that the coloring matter of the urine is derived from the red globules of the blood.

It induces a multiplicity of morbid phenomena, arising from disordered action of the nervous system. The relations of the blood to the functional activity of the nervous system are strikingly shown in the phenomena

pertaining to the latter, which spring directly from morbid conditions of the former. And the special relations between the red globules and the nervous system are shown by the phenomena incident to anæmia. These phenomena are numerous and diversified. The more frequent and prominent are as follows: Mental depression, anxiety respecting health, hypochondriasis, irritable temper, want of buoyancy and energy, a feeling of lassitude, and a painful sense of inertia or indolence. There is apt to be a feeling of incapacity for muscular exertion greater than the actual loss of muscular power. The physical and mental powers are especially depressed during the process of digestion. Palpitations frequently occur, so that organic disease of the heart may be suspected by those not conversant with physical means of diagnosis, and is greatly feared by the patient. Neuralgia in various situations is apt to occur, and in females hyperæsthesia of the abdominal walls, simulating peritonitis. The varied symptoms which have been heretofore described as belonging to spinal irritation, are likely to occur in connection with anæmia. It sustains a causative relation to nearly all the functional affections of the nervous system embraced under the head of the *neuroses*. A large proportion of persons affected with any one or more of this class of maladies are anæmic; and, conversely, a large proportion of anæmic persons become affected with neurotic disorders. It is highly important that this pathological element be taken into account in the management of the neuroses. When it occurs independently of the various affections with which it is connected incidentally, it is characterized especially by phenomena relating to the nervous system. These phenomena may be said to constitute the pathological expression of this morbid condition of the blood.

If it be asked, what is the explanation of the occurrence of these phenomena in consequence of a diminution of the red globules, the pathologist can only say that he may hope to answer the question when the physiologist is able to explain the normal relation between the presence of the red globules and the functions of the nervous system. Pathological facts show that an essential relation does exist between these two anatomical elements of the body; the nervous system depends on this blood-constituent for the manifestations of healthy life, and, hence, a deficiency occasions manifestations of disordered life, or morbid vital phenomena.

The causes of anæmia, when it exists independently of the various affections with which it is associated, are frequently obvious, but in some instances they are not assignable. It is a result of hemorrhages from wounds, flooding after labor and in cases of menorrhagia, or of injudicious bloodletting. It may proceed from deficient alimentation; the food being insufficient in quantity or not sufficiently rich in alimentary principles. It is caused by a loss of certain of those elements of the liquor sanguinis, or blood-plasma, which are necessary to the production of red globules. Thus, frequent causes are prolonged lactation, and a rapid succession of pregnancies. The obvious causes may be arranged into three classes just stated, viz., *First*, causes which involve an actual loss of red globules, as in hemorrhages; *second*, causes involving a defective supply of materials for assimilation; and, *third*, causes which occasion expenditure of those constituents of the liquor sanguinis on which the production of red globules is dependent.

The causes are not always apparent. Anæmia is apt to occur in females at or near the age of puberty, when there has been no loss of blood, no deficiency in alimentary supplies, and no unusual expenditure of blood-plasma. Under these circumstances, it is the prominent feature of the affection to which the name *chlorosis* was applied before the anæmic

condition was fully understood. If this name be retained, it should be considered as denoting anæmia occurring under the circumstances just stated. It appears to be in some way connected with the evolution of the reproductive functions. In some cases it may be accounted for by the derangement of the assimilative functions at this period. In these cases the appetite is poor, the digestion disturbed, and there is apt to be a craving for indigestible, innutritive substances, such as chalk, slate, coal, etc. Addison has described cases of anæmia occurring without any obvious causation, accompanied by general debility which progressively increases, at length ending fatally without appreciable lesions of any of the vital organs. Cases of this kind are occasionally met with, especially in hospital practice. Addison distinguishes them as cases of "idiopathic fatal anæmia." In a certain proportion of these cases, the surface of the body, to a greater or less extent, assumes a dark discoloration or a bronzed appearance, and in several successive cases the suprarenal capsules were found to be more or less disorganized. Addison inferred from these facts a pathological connection between disease of the suprarenal capsules, and the bronzed hue of the skin. Clinical observation, however, shows that the two events are not uniformly associated.

In a large proportion of the cases in which anæmia exists, it is incidental to, or a pathological element of, some other affection. And, as thus associated, it may, or may not, claim the special attention of the practitioner. Of the great number of diseases with which it it connected, either constantly or frequently, the following list will embrace the more prominent:—

1. Tuberculosis.—Anæmia is generally early developed in tuberculous affections, and may precede the deposit of tubercle.

2. Carcinoma.—The pale, waxy, or straw-colored complexion which characterizes some cases of carcinomatous disease, denotes anæmia.

3. The affections embraced under the name Bright's disease.—Associated with œdema of the face, the pallid complexion of anæmia becomes quite characteristic of these affections. The blood-changes which belong to these affections (to be hereafter considered) lead to diminution of the red globules.

4. A host of affections which involve expenditure of other constituents of the blood than the corpuscles, *i. e.*, constituents of the *liquor sanguinis*. Such as chronic dysentery and diarrhœa, chronic pleurisy, purulent formations in any part of the body, leucorrhœa, etc.

5. Affections which involve loss of corpuscles, or hemorrhage, viz., menorrhagia, hemorrhoids, hæmatemesis, etc

6. Affections compromising the assimilative functions by occasioning indigestion, vomiting, loss of appetite, etc.

7. Certain affections of the liver, and especially cirrhosis. It has been supposed that the red globules are produced within the liver. If this be true, diseases of this viscus may lead to their diminution by interfering with their production. But in cirrhosis this effect is due, in a measure, to the obstruction to the introduction of fresh alimentary supplies brought by the portal vein.

8. The periodical fevers, if protracted. The special cause of these fevers may induce anæmia even where the fevers are not developed. Persons inhabiting regions called malarious are apt to become anæmic, although they do not experience fever.

Certain mineral substances introduced into the system lessen the red globules in a notable degree. This is true of lead. Anæmia is a pretty constant element of saturine diseases; and it is observed in persons exposed to lead emanations before becoming affected with the characteristic

diseases. The same is true of mercury. Mercurialization quickly reduces the quantity of red globules in a marked degree.

The diagnostic criteria of anæmia are: *First*, deficiency of the normal coloration of the surface, due to the coloring principle which belongs to the hæmatin in the red globules. The defective color, or pallor, is generally manifest on the ears, the face, and especially the prolabia; it is also apparent on the inner surface of the mouth and on the tongue. *Second*, weakness of the vital organs, denoted by symptoms which observation shows to be associated with paucity of the red globules. *Third*, more or less of the phenomena pertaining to the nervous system which have been mentioned. *Fourth*, the presence, frequently, of obvious adequate causes, such as loss of blood, lactation, frequent child-bearing; or, of affections, to the natural history of which anæmia belongs. *Fifth*, the microscopical appearance of the blood, the red globules appearing to be fewer than in health. *Sixth*, the evidence afforded by a quantitative analysis; but this is too difficult to be available for ordinary clinical purposes.

To the foregoing are to be added the following physical signs. A bellows murmur at the base of the heart and in the larger arteries, carotid, the subclavian, etc. This murmur accompanies the first or systolic sound of the heart, and is usually soft. To constitute evidence of anæmia, there must be wanting the signs of organic lesion of the heart and large vessels. In conjunction with this murmur, a continuous humming sound, sometimes musical, is heard when the stethoscope is applied over the neck, especially on the right side, due to the movement of the blood in the veins, called the venous hum, or, after the French, the *bruit de diable*. These murmurs are distinguished from those denoting lesions, as inorganic or anæmic murmurs. The arterial murmur is present in only a certain proportion of cases; but the venous hum may be found almost invariably, in cases of anæmia, if certain rules be observed in looking for it. The rules referred to are the following: the patient should be sitting or standing with the head turned as far as possible to the left without turning the body, and the stethoscope is to be applied posterior to the sterno-cleido-mastoid muscle. Observing these rules, my experience has led me to consider the venous hum as a very reliable sign of anæmia; that is, it is almost invariably present if anæmia exist, and it is generally wanting if anæmia does not exist. Its disappearance, when cases of anæmia are under treatment, is evidence of the removal of the anæmic state, and in this way attention to this sign is of practical value.

With reference to therapeutics, anæmia constitutes a special indication for treatment when it occurs independently of other affections, or when it is associated, as a prior and causative morbid condition, with disorders of the nervous system. When it is an element of other affections, it contributes, in a greater or less degree, to their pathological effects, and claims a certain share of attention. When it exists alone, or with disorders to which it has given rise, it is generally a remediable condition; but it is otherwise when associated with such affections as tuberculosis, carcinoma, Bright's disease, etc. If not associated with affections of the kind just named, the nutrition of the body may not be impaired, and it is not incompatible with notable embonpoint. When it is the chief condition to be met therapeutically, the first objects are to ascertain and remove, if practicable, the cause or causes on which it depends. The next object is to employ measures to restore the normal quantity of red globules. These measures consist of, *first*, a nutritious alimentation, into which meat should enter largely; *second*, the use of tonics and stimulants to render the digestive functions more active; *third*, iron as a special remedy—the effect

of which is often remarkable; and, *fourth*, a regimen calculated to increase the energy of the assimilative functions, consisting of exercise in the open air, recreation, etc. These different measures are, of course, to be combined. Manganese appears to have an effect in cases of anæmia analogous to that of iron, and may be given, if chalybeate remedies are not well borne, or if they prove inefficient. As the anæmic condition may coexist with any disease; in other words, as persons affected by anæmia may contract a variety of diseases, its existence or otherwise is always to be considered, and its coincidence with different diseases may modify materially their treatment. Bloodletting, and other measures which tend to impoverish the blood, as a rule, are injudicious, whatever may be the disease, if it occur in an anæmic subject. And measures addressed to the anæmia may be called for in certain cases of disease, when, occurring in a person not anæmic or plethoric, the same disease might claim measures of a quite different character.

When simple anæmia exists, and the cause producing it has ceased, as after a hemorrhage, the reproduction of red globules under efficient measures of treatment is rapid. Robin says, after bleeding an animal largely, the return of globules may be almost observed from hour to hour. Simon states that, in the case of a chlorotic girl, an analysis of the blood gave, of globulin, in a thousand parts, 30.860, and, of hæmatin, 1.431. In seven weeks, during which period she had taken two ounces of the tincture of iron and sixty-four grains of the metal, the proportion of globulin had increased to 90.810, and of hæmatin to 4.598. "Before, she was pale and her lips colorless; now, she presented really a blooming appearance." In two cases given by Andral and Gavarret, the red globules were increased, under the use of iron, in one case from 46 to 97, in a thousand parts, in four weeks, and in the other case from 49 to 64 in three weeks. Pure anæmia, with our present knowledge of tonic and analeptic medication, affords an excellent opportunity to display the resources of medical art.

Of the manner in which the causes of anæmia, exclusive of hemorrhage, occasion diminution of the red globules, all that can be said, with our present knowledge, is, that they generally appear to act by impairing the *liquor sanguinis*. Further than this the pathologist cannot go until the physiologist explains how and where the red globules are formed from the elements of the blood-plasma in health.

Anæmia is of more frequent occurrence in the female than in the male. One reason for this is, the normal proportion of red globules is somewhat larger in the male. Another reason is to be found in the fact that, of the causes giving rise to this morbid condition, several are peculiar to females, viz., menorrhagia, leucorrhœa, lactation, and child-bearing.

Changes in the Conformation and Composition of Red Globules.

The foregoing morbid conditions relate to the quantity of the red globules. The question now arises, whether these bodies are not liable to changes as regards their conformation and their composition.

The red globules have a definite form and size, with a certain range of variation within the limits of health. They are circular and biconcave, with a regular contour. In size they vary from $\frac{1}{5000}$ to $\frac{1}{3000}$ of an inch in diameter. Anatomists are not agreed whether they are cells or solid bodies. They are generally regarded as cells; but Robin and, also, other distinguished microscopists of the present time, regard them as solid or semi-solid bodies. When brought into contact with different

substances out of the body, they are found to be readily altered in form, size, and, of necessity, in composition. They imbibe water by endosmosis, becoming swelled and globular. In some fluids they part with a portion of their water by exosmosis, becoming indented, losing their regular contour, and sometimes presenting a wrinkled appearance over their whole surface. The latter changes occur when the globules are contained in urine, and may be witnessed under the microscope by adding a few drops of perspiration. Again, the globules are composed of several constituents, the more important being an albuminous substance externally, forming the cell-wall in the opinion of those who regard them as cells, and a substance, called hæmatin, in which resides the coloring matter, together with iron, fatty matter, etc. Now, the form, size, and composition of these organized bodies are doubtless adapted to certain physiological ends of more or less importance in the economy. And, since they are so easily altered out of the body, it may be inferred that changes in the liquid in which they are suspended (the liquor sanguinis) must, of necessity, give rise to various alterations of their size, form, and composition. This is a rational supposition, but, in the existing state of our knowledge, pathology is wanting in ascertained facts. Their respiratory function, that is, their capacity for absorbing oxygen, is destroyed by certain poisons, *e. g.* carbonic oxide, received with the inspired air, or added out of the body. The effects of various reagents out of the body have been studied; but the circumstances in the living body are so widely different, that we cannot infer the same effects to be produced when the same reagents are administered as remedies, or to lower animals for the sake of experiments. Indeed, experiments of injecting into the bloodvessels various substances have shown the results to be different from, and sometimes quite the reverse of, those produced by applying the same substances out of the body. Future researches may lead to discoveries which will be found to have important pathological bearings; but, at present, no positive conclusions are warrantable.

A morbid condition of the red globules incident to inflammation may be here noticed. These bodies appear normally to exude a viscid or sticky substance in small quantity. This causes them to adhere in rolls or piles, presenting under the microscope an appearance compared to that of rows of coin. In the morbid state of the blood which belongs to inflammatory diseases, this exudation takes place in an abnormal quantity; hence, there is a notable tendency to adhere in rows. A drop of blood under the microscope may thus furnish a diagnostic sign of inflammation.

Apnœa.

The blood contains in health certain gases, viz., oxygen, carbonic acid, and nitrogen. The red globules are agents which absorb and transport these gases. The oxygen of the blood exists exclusively in the globules, although the functional capacity of the latter to absorb this gas depends in a considerable degree upon the serum of the blood. Carbonic acid is held in solution by the blood-plasma as well as by the red globules, the capacity of the former to absorb this gas depending on the presence of the carbonate and phosphate of soda.[1] Oxygen and carbonic acid are received and expelled through the lungs, the interchange of gases with the atmosphere being necessary to the perfection of the blood, and constituting the function called HÆMATOSIS. When these processes are interrupted,

[1] Robin, Leçons sur les Humeurs.

the normal condition of the blood, as respects the gases just named, is exchanged for a morbid condition. The blood does not undergo the conversion from venous into arterial; it presents, in the arteries, the dark color, and essentially the composition and properties of venous blood. It is incapable of sustaining life. This morbid condition of the blood has been called *asphyxia*, a term signifying absence of pulse; a more correct term, now more frequently used, is apnœa, signifying deficiency of breath. Any cause impeding respiration may occasion apnœa. It is the mode of dying in the fatal cases of a considerable number of diseases.

Deficiency of oxygen is the essential feature of apnœa, giving rise to phenomena which will be considered under the head of modes of dying. An excess of oxygen in the blood is probably never an element of disease. An excess of carbonic acid obtains whenever the respiratory function is compromised, and this is an element of apnœa. It is difficult to say what pathological effects are due to an accumulation of carbonic acid, and what to deficiency of oxygen, but the latter undoubtedly has the larger amount of agency in giving rise to the phenomena of apnœa. Regarding apnœa as consisting in a deficiency of oxygen in the red globules, the most complete type of this pathological condition is afforded in cases of death from the inhalation of the carbonic oxide, this gas, when absorbed by the globules, displacing completely the oxygen.

With our present knowledge of nitrogen in the blood, nothing is to be said of its pathological relations.

Leucocythemia.

Of the known morbid conditions affecting the organized or corpuscular constituents of the blood, those which relate to the red globules are the most frequent. There is but one morbid condition relating to the white or colorless globules as yet ascertained; this consists in their abnormal multiplication. The white globules are spherical bodies larger than the red globules, nearly double in size, and they are vastly less numerous. It is estimated that in health they are in the proportion of one to from 300 to 450 red globules. A point of importance, as regards its pathological bearing, is their resemblance to pus-globules. So closely do the two resemble each other that the most practised microscopical observers declare their inability to distinguish the one from the other. Robin and others regard them as essentially identical, and, as already stated, include both under the name leucocytes. According to the observations of Conheim, which seem to have been corroborated by those of other histologists, whenever suppuration takes place in any part, the pus consists, in part at least, of the white corpuscles of the blood, or leucocytes, which migrate through the walls of the vessels, without solution of continuity. Conheim and others affirm that this migration is demonstrable by direct microscopical observation. If this be established it is certainly a highly important discovery, and it settles, of course, the question concerning the identity of the white corpuscles of the blood with the pus-globules; the latter are, in fact, the white corpuscles situated without the vessels.

For our knowledge of the morbid condition consisting in an increase of the number of white globules, we are indebted to the microscope. The existence of such a condition was pointed out by two microscopical observers who were led to the discovery, independently of each other, in the same year (1845), viz., Bennett and Virchow. Virchow designated the condition *Leukæmia*, a term signifying white blood. Bennett applied to it the name *Leucocythemia*, signifying white blood-cells. The latter is the

better term, and is in common use. Both observers at first supposed the abnormal appearance of the blood to be due to the presence of pus.

A certain amount of increase in the number of white globules is not uncommon in pregnancy and in various affections. In order to constitute leucocythemia, the increase should be considerable, amounting to a ratio of, at least, 1 to 20 of the red globules. Cases have been observed in which the ratio was much larger than this, amounting to an equal number of both, and the white even preponderating over the red globules. In all cases the red globules are diminished, and the relatively morbid disproportion is owing in part to this fact. In well-marked cases the gross appearance of the blood undergoes a notable change. It acquires a reddish-gray or a chocolate color. This is particularly observable, after death, in the blood contained in the cerebral veins and sinuses.

This morbid condition of the blood is associated very constantly with enlargement of the spleen, frequently with enlargement of the liver, and, in a certain proportion of cases, the lymphatic glands of the neck, axilla, groin, etc., become more or less enlarged. A distinction has been made by Virchow into splenic and lymphatic leucocythemia, the former being characterized by enlargement of the spleen, and the latter by enlargement of the lymphatic glands. Some cases, however, are characterized by enlargement of both the spleen and the lymphatic glands. In a majority of cases the spleen is alone affected. The lymphatic glands are rarely affected alone, that is, without splenic enlargement. It is stated that the lymphatic variety is also characterized by notable augmentation of the small white bodies called globulins; these are also increased in number, but in a less degree, in the splenic variety. Virchow states that in the splenic variety the white globules are voluminous and have nuclei; whereas, in the lymphatic variety the globules are small. A pathological connection of some sort undoubtedly exists between the enlargement of the parts named and the morbid condition of the blood. What the nature of this connection is, with our present knowledge, can only be conjectured.

Patients affected with leucocythemia are, as already stated, anæmic. They present the pallor of anæmia, together with the phenomena symptomatic of that condition. Febrile movement characterizes certain cases, and in these cases the vital forces are rapidly impaired, and death takes place by exhaustion. Diarrhœa is apt to occur in this class of cases. Other cases are characterized by hemorrhages occurring from the nasal passages or in other situations; and the loss of blood may be sufficient to prove the immediate cause of death. Dyspnœa, independently of any appreciable lesions of the chest, has been observed. Diminution of the vital forces, progressing more or less rapidly, belongs to the history of this condition, which ends fatally sooner or later. It is doubtful if recovery ever takes place in cases in which the condition is well marked. The average duration, before a fatal result, is estimated by Trosseau to be about thirteen or fourteen months.

This condition may be suspected when the appearance and other phenomena of anæmia are associated with considerable enlargement of the spleen or lymphatic glands. It is, however, to be borne in mind that simple anæmia may occur under these circumstances without leucocythemia. Enlargement of the spleen, as is well known, occurs not very unfrequently as a sequel of intermitting fever, and anæmia generally coexists; but observation shows that leucocythemia is developed very rarely in these cases. The diagnostic criterion is the evidence of the augmented number of white globules afforded by microscopical examinations of the blood. Several specimens should be examined under the microscope;

and it is to be recollected that, to constitute leucocythemia, the proportion of white to red globules should at least be as great as 1 to 20. An increase, in the number of white globules more or less, but not sufficiently to constitute leucocythemia, is not uncommon. According to Virchow, the number is increased whenever the lymphatic glands are the seat of irritation. An increase, to cite examples, takes place in typhoid fever, in cases of cancer when the lymphatic glands become involved, and in cases of malignant erysipelas with enlargement of these glands.

After death, in cases of leucocythemia, the right cavities of the heart and the large vessels are sometimes found to contain yellow or yellowish-green collections, soft and viscous, resembling very thick pus. These are formed chiefly by an aggregation into masses of white globules. Similar puriform collections are found in the veins in different situations, but especially in the veins of the cerebral meninges. If blood be drawn during life, the coherent white globules form soft masses, or a layer, of a gray or reddish-gray color, attached to the fibrinous crust at the upper surface of the red clot; and if the fibrin be separated by beating the blood with twigs, the residue being left at rest for some time in a narrow vessel, the white globules collect into a milky or puriform layer at the upper part of the vessel, the red globules, from their specific gravity, falling to the bottom of the vessel.

The question arises, whether there are sufficient grounds to consider this morbid condition as constituting a special disease, or whether it is to be regarded as merely incidental to certain affections. That it is a morbid condition of grave import, is certain; but how much importance belongs to it *per se*, is uncertain. With our present knowledge, we are not warranted in considering it as more than a pathological element of a cachexia, the essential nature of which remains to be determined. The pathologist may expect to be able to understand more fully the nature of this morbid condition when physiologists have established the source and the functions of the white globules of the blood. Robin remarks that leucocythemia is a return to the fœtal state as regards the predominance of these bodies, they being much more abundant in embryonic life, and that this fact affiliates this morbid condition with certain morbid growths characterized by a hypergenesis of anatomical elements which are more abundant in the fœtus.

Since the occurrence of a morbid increase of the white corpuscles of the blood was ascertained by Bennett and Virchow, cases have been reported in which all the phenomena of leucocythemia were present excepting the increase of the white corpuscles. These cases have been called cases of pseudo-leucocythemia. They render it probable that the leucocythemic condition does not constitute the disease, but is merely an incidental feature.[1]

A third constituent of the blood, belonging to the class of corpuscular elements, is called, after Donné, globulins. These minute, spherical bodies, found also in chyle and in the liquid contained in the lymphatic vessels, are notably increased in certain cases of leucocythemia. This single fact is all that is at present known respecting them as entering into morbid conditions.

CHAPTER V.

MORBID CONDITIONS OF THE BLOOD—(Continued.)

Morbid Conditions relating to Fibrin, Hyperinosis, Hypinosis—Coagulated Fibrin within the cavities of the Heart—Coagulated Fibrin within the Bloodvessels—Embolism—Thrombosis—Morbid Conditions relating to Albumen—Dropsy as dependent on Diminution of Albumen—Morbid Conditions relating to Water in the blood—Hydræmia.

HAVING considered, in the preceding chapter, the morbid conditions relating to the organized or corpuscular elements of the blood, it remains to consider morbid conditions relating to the other two divisions of blood-constituents, viz., the organic and mineral substances which enter into its composition. Directing attention to the constituents distinguished as organic, the more important of these are *fibrin* and *albumen*. What are the known morbid conditions relating to these constituents? Proceeding to answer this inquiry, the morbid conditions relating to fibrin will first claim attention.

The fibrin is that portion of the liquor sanguinis, or blood-plasma, which solidifies when the blood is withdrawn from the vessels. In its normal state it is a liquid. It solidifies by an inherent process called *coagulation*. It forms the coagulum or clot which is observed when a quantity of blood is drawn into a vessel and allowed to remain for a few moments. In the process of coagulation, the corpuscular elements become imprisoned, and are retained within the clot; hence the red color. Separated from the corpuscles and other constituents, it is an elastic substance, more or less resisting to pressure, and, examined microscopically, presents an abundance of minute filaments irregularly distributed and interlaced, forming a reticular arrangement: this is called fibrillation. With respect to its sources and uses, physiologists are not agreed; some regarding it as transformed albumen, and constituting, *par excellence*, a nutritive element of the blood; while others suppose it to be effete matter which is to be excreted. The coagulable lymph exuded in certain inflammations is essentially fibrin, and this is probably the basis of all the exudations. With respect to its capability of becoming organized, after it has exuded, pathologists differ, as has been already stated in treating of exudations. In view of the indeterminate state of our knowledge of fibrin, in its physiological relations, the amount of our knowledge of it in a pathological point of view must needs be limited. The only morbid conditions as yet well ascertained have reference to the quantity of fibrin. In certain diseases the fibrin is increased, and in other diseases it is diminished in quantity.

Hyperinosis.

An abnormal increase of the fibrin of the blood constitutes a condition called after Franz Simon, *hyperinosis*. This condition characterizes acute inflammations. The average proportion of desiccated fibrin in health is about two and a half in a thousand parts. In different cases of acute inflammation, the increased proportion is found to vary from three to twelve parts in one thousand. Cases of acute articular rheumatism present the

largest increase of fibrin; pneumonitis ranks next as regards this feature, and capillary bronchitis next. The increase of fibrin is not found to bear any relation to the previous health and vigor of the patient; it is not less in feeble and sickly persons than in the strong and vigorous, when attacked with acute inflammation. The increase takes place when inflammation is developed as an intercurrent affection in the course of diseases in which, if not complicated with inflammation, the fibrin is diminished, *e. g.*, the continued fevers. The hyperinosis has not been ascertained to precede the development of inflammation. The latter is not the effect of the former. The converse is probably true; but, with our present knowledge, it is better to say that the augmentation of fibrin is a concomitant of inflammation, a pathological connection of some kind existing between them. We know too little of the physiological relations of fibrin to understand the nature of this pathological connection. According to Virchow, the hyperinosis in inflammation is due to the production of fibrin in the inflamed parts; and there is a notable difference as regards the amount of fibrin produced in different parts when they are inflamed. This difference Virchow states is in relation with the number of lymphatic vessels and glands in parts; hyperinosis is marked in proportion to the abundance of these in the parts inflamed. Hence, inflammation of the brain is not accompanied by hyperinosis; but the fibrin in the blood is notably increased in pulmonary inflammation, because the lungs abound in lymphatic vessels and glands. According to Virchow, the white globules of the blood are multiplied whenever the fibrin is morbidly increased.

The nature and extent of the pathological relations of hyperinosis not being settled, it is difficult to decide, upon rational grounds, how far this element of inflammation is a source of therapeutical indications. Bloodletting is found to increase the fibrin of the blood, and hence, is not an appropriate remedy for inflammations so far as this element is concerned. Animal diet, in health, more than vegetable, renders the fibrin abundant; hence, theoretically, farinaceous food is suited to the treatment of inflammation. But in starving animals the fibrin increases above the normal proportion; *ergo*, a great reduction of diet is not suited to the treatment of inflammation. The supposition that certain remedies diminish the fibrin of the blood appears to be based on their power of effecting the solution of fibrin out of the body. These effects are quite different. The fibrin in the blood is in a liquid state, and its diminution has nothing in common with its solution after coagulation has taken place. To preserve in the vascular system the liquidity of fibrin, in other words, to prevent coagulation within the heart or vessels, is an object in therapeutics, as will be presently seen.

Hypinosis.

An abnormal diminution of fibrin is called, after Simon, *hypinosis*. This is less frequent than an increase of fibrin, but it probably constitutes a graver morbid condition. It occurs frequently, not constantly, in the continued fevers, provided they are not complicated with acute inflammation of any part. As a rule, the diminution of fibrin is progressive as fevers advance in their career; and the amount of diminution is in proportion to the degree of exhaustion of the vital forces, or adynamia. In the frequent occurrence of hypinosis in these fevers, we have a ground of pathological distinction between them and inflammations.

The decrease of fibrin does not occur as frequently in the eruptive fevers. In variola, owing to the cutaneous inflammation, the quantity is generally

above the normal average. In rubeola it is neither increased nor diminished. In scarlatina it is usually a little below the normal average. It is not diminished in the intermittent fevers.

It is difficult to say how far, if at all, the state of hypnosis constitutes an indication for treatment in the continued fevers. It is not improbable that the importance of animal food in these fevers may have relation to this state, and it has been conjectured that the mineral acids are useful in consequence of their tending to increase the quantity of fibrin in the blood.

Qualitative Changes of Fibrin.

The foregoing changes, relating to fibrin, are quantitative. Qualitative alterations are inferred, but they have not been satisfactorily ascertained. It has been supposed that certain morbid characters in exudations denote perversions of fibrin, but the latter have not been demonstrated. The tuberculous exudation, for example, has been considered as morbidly changed fibrin; this view, in the present state of our knowledge, is hypothetical. The existence of prior blood-changes of any kind, in this or any exudation, has not yet been proven. In short, we have no positive knowledge of morbid changes in the quality of the fibrin of the blood, nor is this knowledge easily obtained, since the characters of this constituent, as it exists in the *liquor sanguinis*, are with difficulty studied. It is obtained, isolated from other constituents, only when coagulated, and is then in an abnormal state. It is not certain that variations observed in coagulated fibrin, either within or without the vessels, represent morbid changes which existed when it was liquid and in circulation.

Thrombosis—Heart-Clot—Embolism.

The recent study of the morbid conditions denoted by, and associated with, the names which form the heading of this section, has led to developments of much pathological interest and practical importance. The writings of some of the older medical authors, namely, Boerhaave, Vansweten, Bonet, and, in the early part of the present century, of Magendie, with several of his contemporaries in France, embrace striking observations and experiments relating to these conditions; but the developments during the past few years, which will be reckoned among the most prominent of the events distinguishing the progress of pathology in our day, are to be dated from the researches of Virchow, in 1847, and those of Kirkes, in 1852. The names thrombosis and embolism were introduced by Virchow. Thrombosis means the formation of a fibrinous clot in an artery or a vein; and the term may also be applied to the coagulation of fibrin within the cavities of the heart. Embolism is an obstruction of a vessel, or of vessels, by fibrin or some other substance which has been transported by the current of the blood from either the heart or some part of the vascular system more or less distant from the seat of the obstruction. A thrombus which obstructs an artery or a vein of sufficient size to be appreciable, is a stationary plug; an embolus obstructing such an artery or vein is a migratory plug. A thrombus becomes an embolus when the obstructing body ceases to be stationary, and is carried along by the blood-current until its course is arrested in a vessel not large enough to admit its passage further onward. It is plain that a migratory plug, or an embolus, can hardly be arrested in its course through systematic veins, since the course of the blood-current is from smaller to larger

vessels. Embolism, therefore, aside from the heart, relates to the arteries with the single exception of the vena porta.

Thrombosis occurring in the cavities of the heart, or heart-clot, first claims notice. The vegetations, concretions, or excrescences which are so often observed after death on the valves, especially within the left cavities of the heart, consist, at least in part, of coagulated fibrin. These constitute a large majority of the arterial emboli, exclusive of those which obstruct the branches of the pulmonary artery. Aside from these examples of cardiac thrombosis, fibrinous masses or clots of considerable size are liable to form in the different cardiac cavities. They were formerly called polypi of the heart. There are two varieties of heart-clot which are easily distinguished from each other. In one variety the clot is essentially identical with that which is formed by the coagulation of blood, in mass, without the body, as after venesection. It is a dark, soft coagulum with, perhaps, a layer of fibrin, the latter being identical with the "buffy coat," as the fibrinous layer in the clot formed after venesection was formerly called. This kind of clot lies free in the cavities of the heart. That is, it is not attached to the endocardium, nor intertwined with the tendinous cords and papillary muscles. It may be formed either after death or during the last moments of life. Yet it is altogether probable that a heart-clot of this kind is sometimes formed when the patient is not in a moribund state, and that it may occasion sudden death. I have met with an example, in a case which will be referred to in connection with articular rheumatism, in which a clot of this kind occurred, and, forming an embolus, obstructed the pulmonary artery, causing sudden death. In general, however, heart-clots of this kind are formed either post-mortem or during the moribund state. Forming in the latter state, they doubtless, not unfrequently, prove the immediate cause of death.

The other variety is of greater pathological and practical interest, because it is the kind which generally exists when death is attributable to heart-clot. To this variety more especially the term thrombosis is applicable. It is distinguished from the other variety by the fact that the clot consists of isolated fibrin, that is, of fibrin, for the most part, free from other blood constituents. The clot is white, dense, adherent to the endocardium, or intertwined with the chordæ tendinæ; and it may show grooves caused by the action upon it of the current of blood. Such a clot must have been formed ante-mortem; and its formation is not unfrequently a cause of death. In this variety of heart-clot, the coagulation does not, as in the first variety, take place at once, but the fibrin is isolated more or less slowly, being deposited in layers, or stratified somewhat as it is within an aneurismal sac. It is evident, however, that the action of the tendinous cords and papillary muscles may be instrumental in the formation of the clot or thrombosis, the fibrin being whipped out of the blood as in the process of obtaining this constituent from blood which has been drawn from the vessels.

The conditions involved in the formation of heart-clot are, *first*, overdistension of the cavities of the heart from an undue accumulation of blood; *second*, an excess of fibrin in the blood or hyperinosis. A *third* condition may perhaps be added, namely, an abnormal coagulability of the fibrin, a condition to which the name *inopexia* has lately been applied. The accumulation of blood occasions a certain amount of paralysis from distension; hence, the contents of the cavities are but partially expelled by the contraction of the muscular walls. There is more or less stagnation in the cavities. Under these circumstances the fibrin may coagulate, and it is isolated by the coagulation taking place slowly, and by the action

of the cords and muscles, especially if the fibrinous constituent of the blood be in morbid excess. These conditions are apt to exist in cases of pneumonitis, and especially when more than a single lobe is involved. The formation of heart-clot will be referred to in the second part of this work, as an accident which occasions death in a considerable proportion of the fatal cases of that disease. It is an accident liable to occur, also, in cases of the disease known as capillary bronchitis, in pyæmia, and, occasionally, in various affections. In addition to the conditions which have been named, there may be others which at present are unknown. Heart-clot, or thrombosis, occurring in cases of pneumonitis and capillary bronchitis, are formed in the cavities of the right side of the heart, because, owing to the obstruction to the pulmonary circulation in these affections, the over-accumulation of blood and stagnation are in the right ventricle and auricle. When the heart-clot or thrombosis is in the cavities of the left side of the heart, there is generally weakness of the walls of the left ventricle and auricle, from either dilatation or fatty degeneration, the over-accumulation and stagnation being dependent on the loss of muscular power incident to these lesions. Prolonged syncope may, perhaps, sometimes lead to a suddenly-formed, soft, dark coagulum, in any of the cavities of the heart. In this way, in 1849, the late Prof. Meigs accounted for sudden death shortly after labor attended with profuse flooding. The late Dr. Simpson, of Edinburgh, reported several similar cases. Other cases have been communicated by Dr. Barnes and Dr. Playfair, of London.[1] Cases of sudden death in diphtheria may be thus explained. Of 580 cases of sudden death analyzed by Ogston, thrombosis of the heart and large vessels therewith connected was present in 63 (10.8 per cent.), and was the cause of death in fourteen.[1]

Passing now to thrombosis of arteries or veins, it involves coagulation of fibrin at the seat of the obstruction, and the latter may be either complete, or more or less incomplete. The conditions leading thereto are, *first*, retardation of the circulation; and, *second*, a lesion, of some kind, of the vessel at the seat of the thrombosis. The diminution of the calibre of a vessel from external pressure, and a partial or complete occlusion by an obstructing substance within the vessel, are causative circumstances; but the rationale of thrombosis, under these circumstances, is the local retardation of the circulation which they occasion. Thrombosis, arising chiefly from feebleness of the heart's action, very rarely, if ever, occurs in arteries; and retardation of the current from this cause is rarely sufficient, excepting in veins at a distance from the heart.

Thrombosis of the iliac or femoral vein constitutes the affection formerly known as phlegmasia alba dolens, occurring especially in puerperal cases; but, also, in some cases of phthisis, and occasionally irrespective of these pathological connections. The chief local effect is œdema, but it may contribute to erysipelas or erythema, hemorrhage, and even gangrene. In arterial trunks, thrombosis is generally a result of atheroma or a calcareous degeneration where the thrombus is formed; these lesions roughening the inner surface, and also, perhaps, diminishing the calibre of the artery. The cerebral arteries are those most liable to thrombosis. In this situation it enters into the causation of hemiplegia and softening of the brain. Thrombosis is often an effect of embolism; that is, a thrombus is formed at the situation in which an artery is occluded by an embolus. Moreover, a thrombus having formed in a vein, the clot subsequently becomes extended in both directions, that is, toward the periphery of the venous circulation,

[1] *Vide* art. by Dr. Lidell, in Am. Jour. of Med. Sciences, Oct. 1872.

and, also, toward the heart. It is easy to see how the stasis in the former of these two directions leads to further coagulation. In like manner the retardation of the circulation in the latter of the two directions may be sufficient to occasion a prolongation of the thrombus. Thus, a clot in the crural vein on one side may lead to secondary coagulations extending to the vena cava of the same side; and these, progressing in a retrograde direction, may extend even to the iliac and the crural vein of the opposite side. These secondary coagulations, in a direction toward the heart, are important as sources of emboli.

The important facts pertaining to the subsequent history of thrombi are as follows: *First*, in the veins they may become dislodged in fragmentary portions, or in mass, and being transported toward the heart, become emboli, which are carried into the pulmonary circulation. *Second*, in either veins or arteries, they may remain indefinitely without essential change, being analogous to foreign bodies. *Third*, they may become organized, then, of course, remaining permanently. *Fourth*, they may undergo granulo-fatty degeneration, forming a puriform detritus which is carried into the circulation. This last named event is important as giving rise to capillary embolisms, infarctus, and events which belong to the history of pyæmia. Referring the reader, for histological details, to works which enter into the subject more fully than is consistent with the plan of this treatise, I pass to the consideration of embolism. It is to be added, that the local effects, immediate and remote, of arterial thrombosis, may be, in the main, the same as those of embolism, and it will suffice to notice their effects in connection with the latter. The chief point of difference, as regards these effects, between arterial thrombosis and embolism is, that the latter occurs suddenly and the former more or less slowly.

Recalling the definition of embolism, namely, complete or partial vascular obstruction, the obstructing body or material having been transported from a situation within the circulatory system more or less distant, a point of difference, in the first place, relates to the size of the vessels obstructed. An embolus may obstruct an artery of large, considerable, or moderate size. On the other hand, granular matter, the detritus of thrombi, or other morbid products, may be brought to parts in sufficient quantity to accumulate and obstruct either arteries of small size or the arterioles. The latter, which is distinguished as capillary embolism, will be noticed separately after having considered embolism in arteries of either large, considerable, or moderate calibre. The emboli in these cases differ as regards their source, the direction which they take, their size, composition, and the morbid effects, immediate and remote, to which they give rise.

The larger proportion of the emboli now referred to are derived from the heart-cavities. They consist of vegetations, masses of fibrin, calcareous matter, or fragments of tissue which are detached and washed away by the current of blood. Generally these are from the left cavities of the heart, and the direction which they take is, of course, into the aorta and its branches. They are carried onward until they reach an arterial branch too small to permit their passage. Here they are arrested, often becoming fixed at a bifurcation, and they obstruct, partially or completely, the flow of blood beyond this point. The vessels into which emboli are especially apt to enter, are the following, enumerated according to their relative liability: The splenic, renal, iliac, carotid, infra-clavicular, mesenteric, and cœliac arteries. Of the carotid arteries, emboli go oftener into the left than the right, the route from the heart through the former being the most

direct. The left iliac artery is more liable in consequence of the iliac vein crossing the artery on the right side.

Emboli of the same description, that is, obstructing arteries of large or moderate size, may also be derived from the right cavities of the heart. The deposit of fibrin in considerable or large masses, and the formation of coagula, that is, heart-clots, occur oftener in the right than in the left cavities. Fragments from the former and the latter in mass may become emboli, which, of course, are carried into the pulmonary artery, obstructing either this artery, its primary divisions, or the subdivisions of the latter. Reference has been made already to embolism of the pulmonary artery, by a recent clot formed in the right ventricle, the effect being sudden death. I have met with an example of complete obstruction of one of the primary divisions of this artery, by a calcareous embolus which was broken off from a similar mass in the right ventricle.[1] Smaller emboli produce, according to their size, obstruction of branches of the pulmonary artery of greater or less calibre. They are more likely to go to the right than the left lung, because the right division of the pulmonary artery is the largest.

Venous thrombosis is another source of emboli, either of the pulmonary or of the systemic circulation. Thrombi in the pulmonary veins, transported first to the heart and thence into the arteries, have, of course, the same direction as those which are formed within the left cavities of the heart; they enter the aorta and become fixed at different points, namely, in the arteries of the spleen, kidneys, brain, etc. It is, however, rare for emboli sufficiently large to obstruct vessels of a considerable or moderate calibre, to originate in the pulmonary veins. On the other hand, it is not uncommon for thrombi formed in systemic veins to become detached, and, carried by the venous current to the right side of the heart, to obstruct the pulmonary artery or its branches. Repeated instances have occurred in which the thrombus, in cases of plegmasia dolens, has furnished emboli of sufficient size to plug the pulmonary artery. The fibrin or clot formed in aneurisms is another source of emboli which take the direction of the systemic arteries. Masses consisting of the white or the red globules of the blood agglutinated together form a rare variety of emboli. Other rare varieties are portions of carcinomatous, cartilaginous, and other morbid growths, which, by ulceration into veins, find their way into the circulatory system. Finally, foreign bodies, through wounds, may become emboli. In another work I have related a case in which a musket ball, inflicting a wound in the neck, passed into the jugular vein, and thence to the heart, becoming imbedded beneath the muscular trabeculæ at the apex of the right ventricle, where it had doubtless remained without doing harm for many years.

The local morbid effects of embolism depend on the size, situation, and vascular connections of the obstructed artery. An embolus obstructing completely the pulmonary artery destroys life in a few moments. One of the primary divisions of this artery, however, may be completely occluded, not only without a fatal result, but without grave symptoms. In the instance which came under my observation, there was nothing to excite suspicion of aught except the tuberculous disease, with which the patient died; and the embolus had evidently obstructed the artery for a considerable time. An obstruction of one of the carotid arteries does not occasion symptoms of any gravity; for the communication through the circle of Willis is so free between the arteries on both sides, that the obstruction is readily compensated for. An obstruction, however, of an artery beyond

[1] *Vide* Treatise on Diseases of the Heart, by the author, 2d edition.

the circle of Willis, owing to a deficiency of anastomosing branches, may give rise, as will be hereafter seen, to apoplexy and hemiplegia. Embolism of the femoral artery may be followed by gangrene of the limb. In this situation sudden obstruction is characterized by intense neuralgic pain. This was illustrated in the case of the late Valentine Mott.[1] Local effects here and in other situations will enter into the consideration of particular diseases in the second part of this work. The immediate effects proceed from the sudden interference with the circulation within the area of the arterial branches beyond the point where the embolus is fixed. Circumscribed ischæmia or anæmia is the primary morbid effect; hence, temporary loss or impairment of functions in the part in which the circulation is suddenly interrupted. This is especially marked in cases of cerebral embolism, in which there is sudden loss of consciousness, accompanied with paralysis. The degree, or intensity of the immediate effects in the brain and elsewhere at the instant when embolism takes place, will depend on whether the obstruction be at once complete or incomplete. The embolus may either fill so completely the artery that the circulation is entirely arrested, or the obstruction may be but partial. If, however, the latter be the case, the obstruction usually becomes, in a short time, complete, in consequence of coagulation caused by the embolus. The immediate effects, under these circumstances, undergo an increase in degree or intensity, the latter being due to the thrombus which is added. Frequently, in examinations after death, emboli, proven to be so by a correspondence as regards their composition and characters with vegetations in the heart or thrombi situated in either the heart or vessels at a distance, are imbedded in a clot evidently formed at the seat of the obstruction. To distinguish, clinically, embolism which is at first partial and becomes complete, from an obstruction which is entirely due to thrombus, is not always practicable.

The loss or impairment of functions within the area in which the circulation is interrupted is sometimes only temporary. The circulation may be more or less speedily restored through anastomosing branches, and thereby the function is recovered. The restoration depends on the abundance of the anastomosing vessels. In general terms, the restoration of the circulation is more difficult, or less liable to take place, in proportion to the distance of the obstructed vessel from the heart, or, in other words, the small size of the artery in which the embolus is seated. The arteries, however, in different organs differ much as respects free communication with each other through anastomosing vessels. In the brain and other internal organs the ischæmia or local anæmia, which is the primary effect of embolism, is a matter of inference; but within the eye it is open to direct observation by means of the ophthalmoscope. In a patient who was seized suddenly with amaurosis of one eye, the late distinguished oculist, Von Græfe, observed, through the ophthalmoscope, a notable exsanguine condition of the retina. On this he based the conclusion that the central artery of the retina was the seat of an embolus. This truly brilliant diagnosis has been corroborated by instances in which, under similar circumstances, the fact of embolism of this artery has been determined after death. It appears, however, to have been ascertained that, at least in certain situations, the ischæmia or local anæmia caused by an embolus, is of short duration. The vessels beyond the seat of the obstruction are filled by collateral arterial branches, and perhaps by a reflux of blood from the veins; but, owing to the loss of the *vis a tergo* beyond the seat of the embolus, the blood stagnates in the vessels; there is a passive

[1] *Vide* New York Medical Record, 1865.

congestion, which may even occasion rupture and extravasation. This congestion, however, does not compensate for the arrest of the circulation, and, notwithstanding the hyperæmia beyond the embolus, there is loss or impairment of function, and certain changes incident to defective nutrition are liable to occur. These changes belong more especially to capillary embolism, but they occur particularly in the brain, where an artery of moderate size, as the middle cerebral artery, is occluded. They are due to either defective nutrition or necrobosis, that is, the loss of vitality within the space in which nutrition is arrested. Softening, sometimes to liquefaction, exemplifies these changes in the brain-substance.

An embolus sometimes excites inflammation of the surrounding tissues, which may lead to suppuration. On the other hand, it may undergo, like thrombi, degenerative changes, being reduced thereby to a detritus which, carried away by the current of blood, may become capillary emboli. In this way, sometimes, the channel of the artery is restored. In general the embolus remains permanently fixed without exciting local inflammation, and the obstruction of the vessel is permanent.

Passing now to *capillary embolism*, under this name more is comprehended than the name would imply. This variety of embolism is not limited to the capillary vessels, nor even to the arterioles, but it embraces embolic obstruction of the smaller arteries. The variety just considered, in which arteries of large or moderate size are obstructed, may be called, by way of distinction, arterial embolism. Capillary embolism, as thus defined, affords an explanation of certain morbid changes occurring in different organs, namely, hemorrhage, softening from granulo-fatty degeneration, abscess, gangrene; and it enters largely into events heretofore considered as characteristics of pyæmia.

The sources of capillary emboli are as follows: 1st. Thrombi in veins, small fragments detached from a venous clot, and the detritus which is left when clots are disintegrated, become capillary emboli. Venous Thrombi in the crural, iliac, and some other veins, have been already referred to; but venous thrombosis belongs to inflammatory affections in different organs, to local injuries, to surgical operations, and other causes. Wherever coagulation in veins takes place, the clot, if it undergo either fragmentary division or disintegration, may lead to capillary embolism. Emboli, thus produced in the systemic veins, are carried by the blood-current to the right side of the heart, and thence into the branches of the pulmonary artery. The morbid effects are manifested in the lungs; but it is conjectured that sometimes embolic matter may pass through the capillary vessels of the lungs, and, gaining entrance into the systemic arterial system, be arrested in other organs; for example, the kidneys in which the arterioles are of smaller size than in the pulmonary organs. The detritus from thrombi formed in the pulmonary veins will, of course, be carried to the left side of the heart, and thence into the arteries, through which it reaches, and is arrested in, different organs, the spleen, kidneys, etc. Thrombi, formed in the portal system of veins, may furnish fragments and detritus which are carried into the vena portæ, and occasion embolism of the smaller vessels of the portal vein within the liver. 2d. Thrombi in the heart-cavities. Thrombi in the right side of the heart lead to capillary embolism within the lungs, and those in the left side lead to embolism of various other organs. 3d. Thrombi in arteries, and also emboli, becoming disintegrated, furnish small fragments and detritus, which give rise to capillary embolism. It is a reasonable conjecture that an arterial embolus of considerable size may be arrested at a bifurcation,

and here be broken up into small fragments by the force of the blood-current, the fragments becoming capillary emboli. Finally, according to Weber, the free oil in the blood sometimes accumulates in the vessels of the lungs to such an extent as to occasion capillary embolism; and air in the blood, which destroys life by obstructing the circulation through the pulmonary capillaries, may also be considered as giving rise to embolism.

The morbid local effects of capillary embolism have been already stated, namely, hemorrhage, softening from degenerative changes, abscess, gangrene. It appears to have been determined by experiments in which small foreign substances were introduced into the circulation, and the abdominal organs exposed to view, that, very quickly after embolism of the smaller arteries is produced, hyperæmia or congestion occurs within circumscribed small pyramidal spaces corresponding to the distribution of the vessels. The pressure of the blood within the hyperæmic spots leads to rupture and extravasation. This is now known as *hemorrhagic infarctus*. By German and French writers, however, the term infarctus is used to embrace the other local changes following capillary embolism, that is, softening, suppuration, abscess, and gangrene. How are these changes to be explained? Impaired nutrition and loss of vitality (necrobiosis) account for the softening and gangrene. Blood extravasated becomes virtually a foreign substance, and its presence may excite suppurative inflammation. But, probably, in some, if not in most, cases, capillary emboli have a pathogenetic agency which is not merely mechanical, that is, their effects are not due to obstruction alone. It is a reasonable supposition that they may have septic or poisonous properties which will measurably explain the local morbid processes attributable to their presence. Different morbid products differ as regards the nature of these morbid properties; and particles of matter, in other words, capillary emboli derived from a part wherein a certain morbid process is going on, will be likely to excite a similar process in the places in which, having been transported thither by the current of blood, they are arrested.

The embolic changes embraced under the name infarctus, in the comprehensive sense of this term, are especially liable to occur in the spleen, kidneys, lungs, liver, and brain. In the spleen, the wedge-like portions so often met with, or "fibrinous blocks," which usually undergo degenerative changes and are at length absorbed, are the sequelæ of hyperæmic stasis and hemorrhagic extravasation. Suppuration and gangrene are here rare results. Essentially the same changes may take place in the kidneys, but small abscesses are less infrequent. They are situated in the cortical portion. In the lungs small extravasations of blood, circumscribed gangrene, lobular pneumonia, and little abscesses, the latter formerly called "metastatic," are local events attributable to pulmonary embolism. In the liver, hemorrhagic infarctus does not occur, but the effects of embolism are the well-known "multiple abscesses" in this viscus. In the brain the embolic changes are punctated or capillary hemorrhage, softening and liquefaction, the latter denoting complete disorganization or necrobiosis. These changes in the several organs just named will enter into the consideration of the local affections therein seated; and capillary embolism will also be referred to in treating of pyæmia.

I have endeavored in this brief section to present an outline of the developments, up to this time, in relation to thrombosis and embolism. At the date of the publication of the first edition of this work, in 1866, the importance of these topics was not fully appreciated by the majority of

medical writers and practitioners. Since that date, facts previously observed have been corroborated, and important additions to our knowledge have resulted from experiments on animals and from clinical observation. I concluded this section in the third edition (1868) by saying that facts were constantly accumulating which tended to show the importance of these topics. At the present time (1872) this statement may be repeated. Much is to be expected from continued researches respecting thrombosis and embolism.

Increase and Diminution of Albumen.

Having considered the pathological relations of fibrin, I pass to the other of the two most important organic constituents of the liquor sanguinis, viz., *albumen*. This exists in the serum of the blood after the separation of fibrin. It exists normally in a liquid state. It does not, like fibrin, coagulate spontaneously, but may be coagulated by heat or the addition of mineral acids, and is then presented as a white deposit. It is found also in chyle, lymph, dropsical effusions, and in various fluids of the body. It is much more abundant in the blood than fibrin, existing in the proportion of from 60 to 70 parts in 1000. The serum of the blood owes to it much of its density, which in health is represented by about 1030. Albumen is doubtless a very important constituent of the blood, but its precise physiological uses and relations are not satisfactorily ascertained. There is reason to believe that it furnishes the pabulum for the development and renewal of the organized or corpuscular constituents, and it undoubtedly constitutes the material for the nutrition of many of the tissues. It has been supposed that the fibrin is formed from the albumen. The two substances are nearly identical as regards their chemical composition.

Albumen is increased in certain diseases, viz., acute rheumatism, pneumonitis, pleuritis, etc.; but, with our present knowledge, it is impossible to say how much pathological importance belongs to this fact. It does not appear to be uniformly increased in inflammation, as fibrin is. It has not, therefore, the same significance as a criterion of inflammation. In short, there are no known special pathological relations of an excess of albumen; and there is no name to denote such a condition.

The pathological relations of an abnormal diminution of the quantity of albumen are more apparent. This constitutes an important condition incident to affections of the kidneys, characterized by the presence of albumen in the urine, or albuminuria. This blood-constituent escaping constantly with the urine, the quantity in the blood is proportionately lessened; hence the density of the serum is lowered. Bright reported a case in which the specific gravity of the serum was reduced, by a deficiency of albumen, as low as 1013.

An important morbid effect frequently follows diminution of the albumen and, thereby, of the density of the blood. Aqueous or serous transudation is apt to occur in the interstices of the areolar tissue and into the serous cavities, giving rise to œdema and anasarca. It thus occasions general dropsy. This effect is doubtless in a great measure due to the diminished density of the blood serum; it becomes unduly aqueous, and filtrates more readily through the tissues. But the transudation is in a measure due to an obstruction to the free passage of the blood through the capillary vessels. Experiments have shown that the presence of fibrin and albumen in the blood facilitates its circulation in the capillary system; hence, when the blood is deprived of a considerable portion of

its albumen, it accumulates in the capillary vessels, and the increased pressure favors transudation, or dropsy.

Diminution of albumen has been observed in various cachectic affections, in some cases of inflammation, in typhus, notably in scorbutus, in puerperal fever, dysentery, etc. This condition occurs whenever the body is insufficiently nourished, either from too little or poor food, or defective appropriation from any cause; also, whenever there is an abnormal expenditure of blood-constituents, as in chronic diarrhœa, copious purulent discharges, etc. The loss of albumen does not bear any constant relation to the number of red globules. It is neither increased nor diminished in chlorosis or anæmia. Nor does it appear to sustain any relation to fibrin. Bleeding, which increases fibrin, appears to lessen albumen, but not in a marked degree.

Of morbid alterations of the quality of albumen, we know nothing positive. That important qualitative changes do occur is highly probable. But, in the present state of knowledge, all is conjectural. When the physiologist develops further information respecting the uses of albumen in health, its metamorphoses, and its relations to other elements of the blood, and to the nutrition of the tissues, the pathologist may hope to understand better than now to what extent and in what modes it is involved in disease.

A substance analogous to albumen, distinguished by not coagulating under the influence of heat, and coagulating imperfectly with the addition of nitric acid, is called *albuminose*. It exists in the blood in the proportion of 4 to 6 parts in 1000. It is found to disappear in the course of diseases in which albumen is diminished. It has no known pathological relations.

Increase and Diminution of Water.

Water constitutes a large proportion of the mass of blood, viz., about 790 of 1000 parts. Obviously a certain proportion of water is essential. If abnormally deficient or superabundant, evils pertaining to the circulation and to changes in the blood itself are likely to follow. These morbid conditions of quantity are incidental to disease. It is doubtful if an excess of water ever occurs save as an incidental morbid condition. The quantity of blood, as already stated, is probably not subject to much fluctuation. It is, however, by no means probable, as stated by Lehmann and others, that the mass is never increased nor diminished. In phthisis and other wasting diseases it is undoubtedly diminished; and it is probable that the amount is sometimes increased. But, as a rule, its normal fluctuations are inconsiderable. If too much liquid be ingested and absorbed, the augmented pressure within the vessels causes exhalation from the pulmonary mucous membrane, the skin, and more especially into the uriniferous tubes of the kidneys, and the balance is speedily restored. On the other hand, if loss be sustained, the deficiency is speedily made good by the absorption of water. In the latter mode the blood may become unduly watery, constituting *hydræmia*. If the globules be reduced in number, the space is filled with water. If albumen be drained away, the serum becomes watery. Hydræmia, therefore, is a substitution, of more or less of the other constituents of the blood by water, and not the blood normally constituted, plus a certain amount of water; it is thus incidental to other morbid conditions of the blood. It is doubtful if water ever remain in excess while the other constituents continue unaffected. Deficiency of water in the blood in a notable degree is incidental to epidemic

cholera. The density of the blood in this disease is greatly increased; it becomes thick, and is with difficulty circulated.

The morbid conditions and relations of several of the most important of the constituents of the blood have now been briefly considered, to wit, the red and colorless globules, or the organized elements, the fibrin and albumen of the liquor sanguinis, carbonic acid gas and oxygen, and water. Numerous constituents yet remain to be noticed. Of these, some are organic, and others inorganic or mineral. Of the remaining organic elements, there are the fatty and extractive matters, sugar and certain principles embraced under the head of excrementitious substances. In the next chapter I shall notice these remaining constituents as arranged in the groups just named.

CHAPTER VI.

MORBID CONDITIONS OF THE BLOOD—(Continued.)

Morbid Conditions relating to Fat—Morbid Conditions relating to Sugar—Diabetes Mellitus—Morbid Accumulations of Excrementitious Principles in the Blood—Uræmia—Excess of Uric Acid in Gout, Uricæmia—Retention of Excrementitious Principles contained in the Vapor of Expiration—Retention of Excrementitious Principles contained in the Perspiration—Reabsorption of Bile, or Cholæmia—Cholesterænia—Morbid Conditions relating to the Saline Constituents of the Blood.

Increase and Diminution of Fat.

FAT enters into the composition of the corpuscular constituents and the liquor sanguinis, the average amount in the whole mass of blood being estimated to be a little over 2 in 1000 parts. The greater part is saponified, that is, in combination with alkalies. Of the fats which are non-saponifiable, with our existing knowledge, the most important is cholesterin. An excess of fat leads to the presence of free fat, in greater or less quantity, in the form of oil-globules. These have been repeatedly observed in diseases. In health the blood-serum is turbid or milky for several hours after a full meal. This appearance has been observed when venesection has been practised under these circumstances. It is due to the products of lacteal absorption which are at this time poured into the blood. This is the explanation of some of the cases of white or milky blood which have been reported by medical practitioners.

The pathological relations of an excess of oil in the blood are very imperfectly known. Clinical observations have shown that it is more or less abundant in acute affections generally. Under these circumstances, it must be chiefly derived from the adipose tissue within the body; hence, the emaciation which accompanies acute affections. It accumulates in the blood of drunkards, leading to that amount of deposit in the adipose structure which constitutes obesity. Lehmann states that this result is not due directly to the introduction of alcohol, but that it occurs only when the liver becomes affected.

Nothing is to be said with respect to our positive knowledge of a mor-

bid deficiency of oil in the blood. Yet, probably, such a morbid condition exists, and has more or less importance in its relation to diseases. This is certainly a fair inference from the benefit derived from cod-liver oil and other fatty substances in tuberculosis, scrofula, and other affections.

Of the non-saponifiable fats, cholesterin alone, with our present knowledge, has important pathological relations. Experiments and clinical observation have shown that this is an excrementitious substance, and a notice of its abnormal accumulation in the blood will therefore come under another division.

Therapeutically, it would seem to be an object to increase the amount of oil in the blood in certain diseases, especially in tuberculosis, and, on the other hand, to diminish the amount in cases of obesity. The latter is also an object in cases of fatty degeneration of the heart and arteries, if it be true, as is highly probable, that this structural change is either dependent upon, or favored by, an excess of oil in the blood. The diminution of oil in the blood is effected by restricting the diet, in a great measure, to nitrogenized substances, avoiding butter, fat meats, sugar, and limiting the amount of farinaceous food. Obesity is not uncommon in middle age, developed to an extent to constitute a morbid condition; and it occurs sometimes in early life, evidently from a constitutional tendency, and may reach an excessive degree, as seen in persons exhibited as objects of curiosity on account of the enormous size and weight to which they attain. Whenever it exceeds the limits of health, it may appropriately claim treatment; and it may often be notably lessened by excluding from the diet fatty articles, and limiting the ingestion of substances readily converted into fat, viz., sugar and starch.[1]

To effect or promote an increase of oil in the blood, oleaginous remedies, and a diet the opposite of that just indicated, are to be employed.

As regards the substances embraced under the head of extractive matters, a few words will suffice. This division includes a variety of undetermined constituents of the blood — undetermined with respect to their nature, source, metamorphoses, relation to different organs, and their uses. Of course they have not, in the present state of our knowledge, any well determined pathological relations. It is not improbable that they play an important part in morbid processes, but nothing has as yet been ascertained.

Abnormal Accumulation of Sugar—Glycohæmia.

Sugar is an organic substance which exists in the blood in health. It is a constituent of the blood in certain portions only of the vascular system, viz., within the portal vein, but more abundantly within the hepatic vein, the vena cava ascendens, the right cavities of the heart, and the pulmonary artery. It is sometimes, but not uniformly, found in the blood generally; and, excepting in the parts just named, when found, the quantity is very small, save as a morbid condition. With respect to the existence and production of sugar within the organism, the discovery by Bernard is of great interest and importance. This distinguished phys-

[1] Mr. Banting, an English non-medical writer, published, some years since, a "Letter on Corpulence," which attracted considerable popular attention. By a system of dietetic management, he reduced his weight within a year 46 lbs. I could cite a case in which, several years ago, I obtained a success not less remarkable. The management of obesity has undoubtedly received too little attention, but it is to be borne in mind that a system of diet suited to diminish an undue accumulation of fat may be, not only inappropriate, but hurtful to persons who do not suffer from corpulence.

iologist has shown that its production is one of the functions of the liver. A certain quantity is received from the sugar and starch contained in the ingesta. But the hepatic vein contains much more than the portal; and it is contained in the former when the ingesta are devoid of both saccharine and amylaceous substances, and when no sugar is contained in the portal blood. It is destroyed during the passage of the blood through the lungs. How is it destroyed? This is a physiological question, but it has important pathological bearings. The explanation which seems most probable is, that it is converted into lactic acid, the latter combining with soda, lime, and potash, forming lactates which are again converted into carbonates, and then again decomposed by the pneumic acid.[1]

It should be stated that Pavy, McConnell, and others deny that a normal function of the liver is the production of sugar. They affirm that during life the liver does not contain sugar, but produces an amyloid substance (hepatic dextrine or starch) which is converted into glucose by the contact of warm saliva, pancreatic juice, or diastase. Pavy claims that the conversion of this substance into sugar is always pathological. It may be added that, according to Robin, the glycogenic function of the liver is performed by the hepatic lobules, the bile being secreted by the membrane lining the hepatic ducts.

In health, sugar is not eliminated from the body, but, as a symptom of disease, it may exist in great abundance in the urine, in other secretions, and in exhalations; and under these circumstances, the blood everywhere throughout the body contains it. This constitutes the morbid condition commonly known as diabetes mellitus.

In cases of diabetes, sugar exists in the urine, in other secretions, and in transuded liquids, in consequence of its existence in the whole mass of blood. Diabetes is not a disease of the kidneys, as it was formerly regarded; these organs merely excrete sugar contained in the blood brought to them by the renal arteries. The sugar in the renal blood increases the functional activity of the kidneys, acting like a diuretic, and, hence, the quantity of urine is greatly increased. An increased quantity of urine containing sugar in abundance thus becomes the diagnostic criterion of diabetes. The abnormal presence of sugar in the blood is expressed by the term *glucohæmia* or *glycohæmia*.

Why is it that the blood in the general circulation becomes saccharine in this disease? Either the liver produces too much sugar, or the processes by which it should be made to disappear from the blood in the lungs are imperfect. Our present knowledge does not perhaps enable us to decide between these two explanations, and both may concur in some cases; the first, however, is the more rational, if it be true, as estimated by Bernard, that in some cases of diabetes a much larger amount of sugar is excreted by the kidneys than is formed by the liver in health.

Moreover, certain facts render it not improbable that a prior morbid condition of the nervous system may be involved. Bernard ascertained that, by irritating the medulla oblongata at the point of connection of the pneumogastric nerve, sugar appears in the urine. A transient attack of diabetes may in this way be produced at will in an inferior animal. Hence, it may be conjectured that diabetes, occurring spontaneously, is an affection of the nervous centre, an abnormal influence being transmitted to the liver through the pneumogastric nerve.

Were the seat and nature of diabetes established, our knowledge might, perhaps, lead to rational indications for treatment. As it is, the thera-

[1] Robin and Verdeil, Chimie Anatomique.

peutics of the disease is quite unsettled. It is a very grave disease, persisting in the great majority of cases, and proving fatal sooner or later. A temporary and partial relief is, in general, only attainable; and this is effected by different means, so that the success of a particular mode of treatment does not reflect much light on the pathology of the disease. Inasmuch as a considerable portion of the sugar is derived from the ingesta, one point in the management is to cut off or diminish the supply of sugar in the food. In this way, the quantity of urine, and the amount of sugar which it contains are generally lessened. But this measure of treatment is directed, not against the primary or essential morbid condition, but only against an effect or symptom; for the presence of the sugar in the blood is dependent on some prior morbid condition. The saccharine blood is the ultimate, appreciable, morbid condition, in the existing state of our knowledge, but this is evidently a result of some deeper change which has not yet been ascertained. Alkaline remedies, continued, with occasional intermissions, for a long time, as recommended by Trousseau, I have known to prove remarkably useful, but in some cases they are attended with no benefit. This treatment is based on the hypothesis that the sugar received into and formed within the system is not destroyed owing to the want of alkalies in the blood. Rennet has been proposed with a view to promote lactic fermentation, and its usefulness is said to be shown by the results of clinical experience. Remedies addressed to the nervous system are found to diminish the quantity of sugar excreted. Opium is generally beneficial. Strychnia is sometimes notably so.

The treatment of this disease will be more fully considered in the second part of this work. These different measures are here mentioned in illustration of the fact that clinical experience appears to show the utility of methods of treatment based on different views of the pathology and seat of the disease.

Sugar may appear transiently in the urine, in small quantity, in various diseases, and, under these circumstances, has no more pathologieal importance than the occasional appearance of a trace of albumen. The statement made a few years ago by Reynoso that the urine is habitually saccharine in affections which compromise the respiratory function, has not been confirmed by the observations of others. A trace of sugar may be found in the urine of healthy persons after certain kinds of food, after the inhalation of chloroform, and when certain remedies have been given, especially the ethers. It is also found sometimes in considerable abundance for a short period when the system is disturbed by strong mental emotions.

Accumulation of Excrementitious Principles in the Blood—Uræmia.

Certain morbid conditions of the blood consist in an undue accumulation of excrementitious substances. And, of these, first in importance are the organic constituents of the urine, viz., urea and uric acid. These, as well as all excretory products, are pre-formed in the blood, not produced within the glands, as was formerly supposed.[1] They exist, therefore, in the blood in health, and it is their accumulation in abnormal quantity which consti-

[1] It has been claimed that experiments made by Oppler, Schottin, Perls, and Zalesky, go to show urea and uric acid to be produced within the kidneys; and that the morbid phenomena attributed to uræmia depend on the accumulation in the blood and tissues of creatine, creatinine, and other primary products of tissue metamorphosis. *Vide* Roberts's Treatise on Renal and Urinary Diseases.

tutes the morbid condition. The excrementitious substances just named are distinguished as nitrogenized, and consist of effete matter derived from the nitrogenized tissues of the body. Their existence in the blood in health has been fully demonstrated; and their undue accumulation in certain affections of the kidneys has been proved by direct observation. Deficient excretion of urea occurs in acute inflammation of the kidneys or nephritis, in the affection commonly known as acute albuminuria, and as a result of the lesions embraced under the name chronic Bright's disease. Under these circumstances the urea accumulates in the blood, and gives rise to the condition called *uræmia*. There is no evidence that this condition is ever due to an excessive production of urea of the blood. In all cases it is a consequence of the excretory function of the kidneys being either arrested or inadequate to a proper elimination of this excrementitious substance.

Uræmia is a form of blood-poisoning, or *toxæmia*, entering largely into the causation of morbid phenomena, and consequently of great importance in its practical relations. Our present knowledge of it has been recently acquired, and although by no means so complete as could be desired, constitutes one of the most prominent of the characteristics of medicine at the present time, as compared with the past. The effects of this morbid condition are manifested especially in phenomena pertaining to the nervous system, coma and convulsions of an epileptiform character constituting the graver of these. These phenomena are apt to precede a fatal termination. Coma and convulsions occurring either with, or subsequent to, scarlatina with renal complication, in nephritis, in Bright's disease, and puerperal eclampsia, are due to uræmic poisoning. The urea accumulating beyond certain limits acts upon the nervous system in a manner analogous to certain poisons introduced from without the body—for example, strychnia. Its mode of action is not explicable with our present knowledge. The question has arisen whether it acts directly as urea, that is, without having undergone in the blood any change. According to Frerichs, it is converted in the blood into carbonate of ammonia, a substance with which it is chemically nearly identical, and it becomes poisonous only after this conversion has taken place. Frerichs claims to have established the correctness of his opinion by experiments on inferior animals and clinical observation. The admirable experiments of Hammond, however, disprove this hypothesis.[1]

Clinical observation shows that various inflammations are apt to be developed as results of uræmia, more especially serous inflammations, viz., pleuritis, pericarditis, and peritonitis. It is supposed to stand sometimes in a causative relation to pneumonitis. Amaurosis is an occasional result. It is one of the pathological conditions under which neuralgia occurs. Other results denote efforts for the vicarious elimination of urea. Persistent vomiting and purging belong to the clinical history of uræmia; and these symptomatic events are due to efforts of elimination of the urea through the gastro-intestinal mucous membrane. The experiments of removing the kidneys of inferior animals, by Prevost and Dumas, Bernard and Barreswill, Hammond and others, show that, under these circumstances, urea accumulates in the blood; after a time vomiting and purging occur, and either urea or the carbonate of ammonia is found in the contents of the alimentary canal; finally, this vicarious elimination being insufficient to prevent an accumulation from reaching the point necessary for the production of poisonous effects, convulsions and coma ensue, and death

[1] Physiological Essays.

speedily follows. The same consequences take place when the excretion of urea is prevented by certain diseases of the kidneys.

In order to ascertain the existence of uræmia, an analysis of the blood may be made; but this mode is hardly available for ordinary clinical purposes. The existence of uræmia may be inferred whenever, in connection with its characteristic pathological effects, the secretion of urine is suppressed, or the quantity greatly diminished. Urea, however, may be wanting in the urine, although the quantity of the latter be not much, if at all, diminished. The urine is of a low specific gravity when the urea is deficient, and, as the deficiency of urea is generally associated with albuminuria, the presence of albumen in the urine, with diminished density, renders it probable that uræmia exists. For positive proof, the urine may be analyzed with reference to the quantity of urea which it contains. If not adequately excreted by the kidneys, urea must accumulate in the blood, and if not eliminated vicariously through some other channel, the pathological effects of uræmia must sooner or later ensue.

The therapeutical indications pertaining to uræmia are, *first*, to endeavor to promote the excretion of urea by the appropriate emunctories, viz., the kidneys, and, *second*, to favor its vicarious elimination. The first indication relates to the use of diuretic remedies, which, unhappily, are often inoperative when the kidneys are much diseased. The second indication calls for hydragogue cathartics and sudorific measures, urea being eliminated through the intestinal canal and the skin. These measures are to be relied upon whenever the prompt and efficient elimination of urea is indicated. The spontaneous efforts of elimination through the stomach and bowels are not to be too much interfered with. There are no known means of neutralizing the urea in the blood, or protecting the system against its poisonous effects.

Uricæmia.

Uric acid, the other important organic constituent of the urine, exists in a small quantity in the blood in health, as shown by the researches of Garrod. Garrod has also shown that it exists in an abnormal quantity in gout. He regards this morbid condition as sustaining a special causative relation to the phenomena of gout.[1] Uric acid enters into the composition of the deposit around and within the joints, in the *tubuli* of the kidneys, and sometimes in other situations, which is characteristic of this disease. Moreover, Garrod's researches show that the excretion of uric acid in the urine is often notably diminished during a paroxysm of gout, and that this constituent of the urine is habitually lessened in the chronic form of the disease. The kidneys in persons affected with gout seem to lose, to a greater or less extent, the faculty of excreting uric acid, the faculty of excreting urea remaining intact. It is an interesting fact that in acute rheumatism the uric acid in the blood is not in excess, and the quantity in the urine is apt to be increased. This fact, according to the author just named, goes to establish the non-identity of gout and rheumatism, although as regards their local manifestations, these two diseases bear to each other a close analogy.

Assuming that the pathology of gout involves an excess of uric acid in the blood, the question arises whether this excess be due to an accumulation from insufficient excretion, or whether the uric acid may not be produced

[1] The Nature and Treatment of Gout and Rheumatic Gout, by Alfred Baring Garrod, F.R.S., etc. London, 1859.

in too large quantity. Garrod holds the opinion that both explanations are applicable. He thinks, also, that a reduction of the alkaline condition of the blood favors the deposition of the urates, which experiments show to be precipitated out of the body in a solution to which a weak acid is added, whereas they are held in solution so long as the fluid remains alkaline. This view of the pathology of gout is rendered highly probable by the facts which Garrod's researches appear to establish. It remains to determine whether an excess of uric acid in the blood be not a morbid condition existing in other affections as well as in gout. Garrod has found it to exist in cases of lead-poisoning Continued research may show that this is not the only exception to its being a condition peculiar to gout, and it may be found to stand in a causative relation to other phenomena than those which characterize this disease. An excess of uric acid (in the form of urates) in the blood, constituting a condition differing from uræmia, it is desirable to distinguish it by a name, and if I might venture to coin a term, I would propose for this purpose, *uricæmia.*

The therapeutical indications in this condition are to introduce alkalies into the blood, in order to hold the urates in solution, and to promote elimination through the kidneys by diuretic remedies. Clinical experience appears to sustain the correctness of these indications. Dr. Buckler, of Baltimore, has suggested, as a remedy for gout, on chemical grounds, the phosphate of ammonia, the ammonia being supposed to combine with the uric acid, and the phosphorus with the soda, forming two soluble compounds which are readily eliminated by the kidneys. Various clinical observers have borne testimony to the utility of this remedy.

Accumulation of the Excrementitious Principles of Expired Air, Perspiration, and Bile—Cholæmia—Cholesteræmia.

In addition to the kidneys, the lungs, the skin, the liver, and, perhaps, the mucous membrane of the intestinal canal, take part in the elimination from the body of excrementitious principles; and an arrest or impairment of the excretory functions of these organs may lead to an accumulation of noxious matters in the blood. It remains to notice briefly the supposed morbid conditions thus produced.

The most important purpose of respiration, so far as excretion is concerned, is the elimination of carbonic acid. The undue retention of this gas has already been noticed as an element of apnœa. The vapor of the expired breath, called the pulmonary transpiration, contains other excrementitious principles. It is well known that various medicinal substances and certain constituents of articles of food escape through this channel; and the retention of the indeterminate substances contained in the extractive matters of the expired moisture may give rise to noxious effects, either directly or by inducing catalytic changes in the blood. But we have no positive knowledge with regard to blood-poisoning from this source.

The chief purposes of the perspiration appear to be the elimination of water and the regulation of temperature. The proportion of solid matter in the perspired fluid is small, chloride of sodium being the largest ingredient. The excrementitious principles which, if retained, may give rise to morbid conditions of the blood, must be contained in the extractive matter of the sweat. The odor frequently accompanying emanations from the skin shows that something is eliminated, which, we may imagine, would be noxious if retained. It is generally thought that important excrementitious principles are eliminated by the skin; but this is a con-

jecture rather than a conclusion based on actual knowledge. Observation appears to show that disease not unfrequently originates from suppression of the cutaneous transpiration. It is a popular notion that many diseases are thus produced. The importance of this as a source of disease is doubtless vastly overrated; yet the general opinion is not devoid of foundation. The occurrence of disease, however, in consequence of the action of cold on the surface, is not to be explained exclusively on the hypothesis of the retention of excrementitious principles. When the functions of the skin are arrested by cold, there are two other modes in which we may suppose disease to be produced. One of these relates to the circulation. The blood, being driven from the surface, must accumulate in the internal organs, giving rise to congestion. The other mode relates to the increased supplementary activity of certain organs, to compensate for the deficient elimination from the skin. The kidneys and lungs antagonize the skin in this regard, and if the kidneys fail, the labor of performing the eliminative function of the surface falls upon the lungs; hence, disease of the latter—an excessive physiological activity of an organ being liable to end in a pathological condition. Perhaps these two modes of operation will account for the production of disease in consequence of suppressed cutaneous transpiration, in the majority of the cases in which disease is thus produced.

With our present knowledge respecting bile, it is to be considered as embracing both excrementitious and recrementitious principles. The biliverden, or coloring matter, and the salts peculiar to the bile, viz., the glyco-cholate and tauro-cholate of soda, do not exist preformed in the blood, but they are produced within the liver. On the other hand, cholesterin, which enters into the composition of bile, does not exist in the blood. This constituent, there is reason to believe, is excrementitious. Late experimental researches appear to have established that it is produced in the destructive assimilation of nervous tissue. It is contained more abundantly in the venous blood coming from the brain than in the arterial blood going to the brain. It is found in larger quantity in the portal than in the hepatic vein; and this fact, taken in connection with the fact of its presence in the bile, goes to show that one of the functions of the liver is the elimination of this substance. It appears in the feces in the form of another variety of non-saponifiable fat, called *serolin*, which it has recently been proposed to call *stercorin*.[1] Other substances, viz., *leucine* and *tyrocine*, have been found in bile; and it is probable that these are excrementitious, but their physiological and pathological relations are not yet satisfactorily ascertained.

The presence of bile in the blood constitutes the morbid condition called *cholæmia*. It will be considered, hereafter, as an individual disease, under the name *icterus* or *jaundice;* but the condition is incidental to various affections. Cholæmia is manifested by the yellow or greenish coloration of the conjunctiva and cutaneous surface. As in the case of sugar in the general circulation, the bile is eliminated, to a greater or less extent, by the kidneys, and it is therefore found in the urine in abundance. In the great majority of cases, the condition depends on obstruction of the passage of the bile from the liver to the duodenum. It rarely accompanies certain structural affections of the liver, such as cirrhosis, fatty deposit, carcinoma,

[1] *Vide* article entitled "Experimental Researches into a new Excretory Function of the Liver, consisting in the Removal of Cholesterin from the blood, and its Discharge from the Body in the form of Stercorin." by Austin Flint, Jr., M.D., etc., *American Journal of the Medical Sciences*, October 1862.

tuberculosis, etc. These facts go to show that it occurs from the re-absorption of bile after the secretion has taken place, and not from defective secretion. Defective secretion, however, either with or without obstruction and re-absorption, doubtless occurs, and, under these circumstances, the excrementitious constituents of the bile, which are performed in the blood, *e. g.*, cholesterin, will accumulate if not vicariously eliminated. The non-secretion of bile has been called *acholia*. Occurring either in cases of icterus or independently of the phenomena of the latter, it may give rise to a condition of the blood more immediately serious than the condition caused by the re-absorption of bile, or cholæmia.

Cholæmia does not, in general, occasion serious effects. Patients are not always greatly incommoded by this condition. The re-absorbed bile appears to exert a narcotic influence, more or less marked, on the nervous system, producing dulness of the mental faculties, a disposition to sleep, slowness of the pulse, and torpor of the functions generally. If, however, the condition be prolonged, hemorrhages are apt to occur, and the kidneys may become affected so as to lead to uræmia.

All clinical observers have been led to observe exceptional cases of cholæmia, in which the bile appears to exert an intensely noxious influence on the nervous system, inducing coma and death. Excluding cases in which the supervention of uræmia may account for these results, they may be attributed to the retention and accumulation in the blood of the excrementitious principles of the bile, and perhaps especially cholesterin. There are grounds for believing that the accumulation of cholesterin in the blood gives rise to a special form of blood-poisoning, to which the name of *cholesteræmia* has been applied. The grave consequences of acholia may be explained in this way. It is to be borne in mind that acholia is not necessarily associated with cholæmia; in other words, there may be non-secretion of bile without, as well as with, obstruction and re-absorption, the latter only giving rise to the phenomena of jaundice. It is not improbable that a deficient elimination of cholesterin may occasion more or less of those indefinite symptoms which are commonly embraced under the name *biliousness*, and which are relieved by remedies supposed to act upon the secretory function of the liver.[1]

It has been supposed that one of the functions of the intestinal canal is elimination of excrementitious principles from the blood. The fluid formed by the glands of Lieberkuhn, in the small and large intestine, may be in part excretory. This, however, is at present only a conjecture. There are no known facts which show that the retention of principles contained in the intestinal juice constitutes a morbid condition of the blood.

Saline Constituents of Blood.

Morbid conditions pertaining to the *saline constituents* of the blood will claim very brief notice, because, although it is highly probable that they are the seat of important changes, we have very little positive knowl-

[1] M. le Dr. Picot, Professor of Histology, in Tours, has reported a fatal case of malignant or grave icterus, the history characterized by notable torpor of the mental faculties, with mild delirium, and, at length, complete coma, the post-mortem examinations having been made with special reference to the existence of cholesteræmia. A chemical examination of the blood and the brain, in this case, showed a large accumulation of cholesterin. Dr. Picot concludes that this case goes to confirm the existence and the importance of cholesteræmia as a morbid condition of the blood. *Vide Journal de l' Anatomie et de la Physiologie; publié par M. Charles Robin, No.* 3, *Mai et Juin*, 1872. *Paris.*

edge respecting them. Enumerated in the order of their relative quantity, the more important of the salts in the blood are, the chloride of sodium, carbonate of soda, chloride of potassium, phosphate of soda, and sulphate of potassa. The average amount of the salts, collectively, in healthy blood, is estimated to be from 7 to 8 in 1000 parts. Our knowledge of the physiological changes and uses of these constituents is far from complete, but they are manifestly important as supplying matter required for the several tissues and for various secreted fluids. Moreover, they are concerned in the preservation of the red globules, in the solution of albumen, in maintaining the alkalinity of the blood, in the regulation of the passage of liquids through the coats of the vessels in the processes of endosmosis and exosmosis, etc.

The alkaline salts (carbonate of soda and potassa) have been found to undergo considerable fluctuations in disease. They are much diminished in inflammations, and increased in the eruptive and continued fevers. The supposed utility of mineral acids in the essential fevers is consistent with a super-alkalinity of the blood. As already stated, a deficiency of the alkaline salts is supposed by Garrod to be concerned in the deposition of uric acid in gout. In articular rheumatism the employment of alkaline remedies, as advocated by Fuller and others, is based on the theory of neutralizing an acid, supposed to be the lactic, in the blood. The pathology of diabetes has been thought to involve a deficiency of alkalies in the blood, and hence the value of alkaline remedies in certain cases.

The researches of Garrod appear to show that a deficiency of potassa constitutes an important element in scorbutus; and, according to this pathological view, the efficacy of lemon-juice and the various anti-scorbutic vegetables is due, not to the presence of an acid, but to the salts of potassa which they contain. This view is sustained by the usefulness of the salts of potassa employed as remedies in this disease.

Finally, the phenomena pertaining to the blood and circulation in that remarkable disease, epidemic cholera, are measurably due to the loss of saline constituents contained in the serous transudation into the alimentary canal.

CHAPTER VII.

MORBID CONDITIONS OF THE BLOOD—(Concluded.)

Morbid conditions due to the presence of morbid products, intrinsic and extrinsic—Pyæmia—Putrid infection of the blood, or Septicæmia—Matter of contagion—Viruses—Infectious Miasms—Venoms—Poisons, palpable, and impalpable or miasms—Zymosis—Considerations which lead to the inference of the prior existence of a constitutional or general morbid condition, or indeterminate blood-changes, in various local affections.

THE morbid conditions of the blood which have been thus far considered relate to its normal constituents. The presence in the blood of morbid products gives rise to conditions which are now to be noticed. The morbid products which may be contained in the blood are of two kinds, viz., 1st, those formed within the body of the person affected, and, 2d, those derived from the body of another person.

Pyæmia—Septicæmia.

A brief enunciation of views seemingly most consistent with our present knowledge of the morbid conditions to which the above terms relate, is all that the scope of this work will allow. More than this is hardly required in a treatise on the principles of medicine, inasmuch as these morbid conditions enter so largely into surgical pathology.

The name pyæmia signifies pus in the blood. Purulent infection of the blood is a synonymous phrase. When the name was introduced by Piorry the absorption of pus was supposed to take place without disintegration of its corpuscular constituents. And it was supposed that after gaining entrance within the bloodvessels the pus was deposited in different situations, and that in this way were produced the purulent collections in the lungs and elsewhere known as "metastatic abscesses." After the advent of microscopy into pathological researches, it appeared to be clear that the size of the pus-corpuscles must prevent their passage from without into the blood otherwise than through openings into the vessels resulting from wounds or ulceration, and, also, that, owing to their size, they could not pass through the coats of vessels and be deposited in different organs. Moreover, it became apparent that pus-corpuscles and the white corpuscles of the blood are identical, and the name leucocytes was applied to both. Until within a late period, suppurative phlebitis was supposed to occur not unfrequently, and, pus being produced in consequence within the veins, its presence in the blood was often thus accounted for. This view, held by many when the first edition of this work was published (1866), seems now to have been in a great measure abandoned by most pathologists, the researches of Virchow and others appearing to prove that inflammation of the lining membrane of the veins is rare. It seems, also, to be proven that coagulation of blood in veins is not, as was formerly held, an effect of phlebitis, but, when the latter is associated it is secondary to the coagulation, and that the lining membrane of the veins is not the one most likely to become inflamed. Again, the facts which have been ascertained respecting thrombosis and embolism (*vide* page 71, *et seq.*), have seemed to account, in a great measure, for the production of "metastatic abscesses," these constituting a characteristic feature of pyæmia. These results of pathological studies have, of late, unsettled the views concerning pyæmia which were held when the name was introduced. In so far as concerns pus-corpuscles being present in the blood, it is denied that this constitutes the essential morbid condition in cases of so-called pyæmia. Admitting pus-corpuscles and the white corpuscles of the blood to be identical, their accumulation in excessive quantity is the morbid condition already noticed under the name leucocythemia, and in this affection the symptomatic phenomena attributed to purulent infection of the blood are not present.

On the other hand, as supporting the doctrine of pyæmia, microscopical observations still more recent than those just referred to, seem to have ascertained that the purulent collections, that is, abscesses, in different situations consist, at least in part, of the white corpuscles of the blood, or leucocytes, which, under conditions of disease, do pass through the coats of the vessels without any solution of continuity, and migrate into the surrounding tissues. It is claimed that passage from within outward, and *vice versâ*, has been demonstrated by direct observation. Admitting this, the absorption of pus, together with its disposition to form "metastatic abscesses," should no longer be considered a physical impossibility. That pus sometimes enters into the circulation through openings into

vessels by orifices resulting from wounds and ulceration is certain; and clinical observation shows that the symptomatic phenomena of pyæmia are most likely to be developed when the entrance of pus in this way is especially apt to occur, namely, in certain diseases of the bones. Again, although pus-corpuscles are identical, as far as microscopical characters are concerned, with the white corpuscles of the blood, it is easy to understand that the former may have acquired toxical properties not belonging to the latter, properties not appreciable by the microscope, nor by chemical examination. In these toxic properties may consist their pathogenetic power. Moreover, it is evidently incorrect to consider the corpuscular component as alone constituting pus. The liquor-puris is an essential constituent of a purulent liquid, as much as the liquor-sanguinis is of blood. Now, it is not unlikely that the toxic properties of pus belong especially to the liquor-puris. Finally, by the injection of pus into the blood, in inferior animals, the phenomena of pyæmia, during life, and the anatomical characters after death, may be produced. These facts and considerations go far to sustain the doctrine that in cases of so-called pyæmia there is, in fact, a purulent infection of the blood.

Regarded from a clinical point of view, pyæmia denotes an affection undoubtedly involving a special morbid condition of the blood, and presenting certain distinctive features relating to its causation, its symptoms, its course, and the appearances after death. In general, the causation is distinctly traumatic. In most cases it follows an accidental wound or a surgical operation, and more especially wounds or operations involving a bone of considerable or large size, for example, the femur. It may follow inflammations which are not of traumatic origin. It is one of the affections which are embraced under the name puerperal fever, that is, it may arise from uterine morbid conditions shortly after parturition. Occasionally it occurs when there is no apparent causation. It is then distinguished as idiopathic or spontaneous pyæmia. In typical cases the local causation being obvious, it is developed consecutively to suppuration; hence, the pyæmic phenomena are not manifested until after several days from the date of a wound or surgical operation, which, meanwhile, has become notably tender and painful, with more or less diffusion of the inflammation.

The clinical history is characterized by repeatedly recurring chills, more or less pronounced, occurring irregularly, and followed by profuse sweating. Fever is persistent, varying, as shown by the thermometer, in different cases, the greatest amount of heat being directly after the chill, the mercury rising, at this time, from 104° to 108°. The skin becomes sallow, and not unfrequently distinctly jaundiced. The intelligence is but little or not at all disturbed. There may be pain in the chest, with cough and frequent respiration; and physical exploration may show pleuritis with effusion, or bronchial râles with broncho-vesicular respiration at different points on either side of the chest, or on both sides. Pain may be felt in the knee and other joints, and effusion within the synovial membrane may be discovered. At length persistent collections, not preceded by the usual local symptoms of phlegmonous inflammation, "cold abscesses," as they are sometimes called, may be found in different situations, sometimes in one or more of the limbs, and sometimes on the trunk. The formation of purulent matter in these situations is sometimes extremely large. Suppurative inflammation of the eye, leading to sloughing and the evacuation of the humors, is an occasional event. This has been observed chiefly in cases of pyæmia following parturition. The affection in most cases runs a rapid course, the duration being from eight to ten

days. With less intensity the disease may continue from two to four weeks, and occasionally it becomes chronic, lasting for several months. In the latter cases the duration depends on the secondary abscesses, which, by their continuance, become properly sequels of the pyæmia. In the vast majority of cases the affection ends fatally. Death seems, in some cases, to be attributable to asthenia incident to the morbid condition of the blood, sometimes to heart-clot, and sometimes to the secondary affections of the viscera. In the cases which recover, the local effects consist chiefly of subcutaneous purulent collections and arthritic suppuration. The foregoing enumeration of the leading symptomatic events embraces points by means of which, generally, the discrimination of pyæmia can be made without difficulty.

The most characteristic lesions found after death are circumscribed inflammations and multiple abscesses in different internal organs, but more especially in the lungs. In these organs they generally vary in size from that of a filbert to that of a pea. They vary in number in different cases. They are situated especially in the lower portion generally of both lungs, but they are sometimes limited to one lung. The appearances differ in different cases, and the differences are sometimes exemplified in the same case. In the portions affected, there may be intense congestion or an extravasation of blood. The appearances may be those of pneumonia in the second stage; collections of purulent matter may be found, as expressed by the term "multiple abscesses," and the tissues are sometimes in the state of gangrene or sloughing. Patches of congestion, inflammatory exudation and suppuration, varying in size from a hen's egg to a filbert, and more or less numerous, are disseminated throughout the liver in certain cases. This organ sometimes contains an enormous amount of purulent matter. The kidneys, in some cases, contain small abscesses, situated in the cortical portion. In the spleen, either extravasations of blood or the so-called fibrinous blocks are often found. Numerous extravasations of blood may be found on the surface of the heart. Ulcerations of the cæcum and colon are sometimes observed. The anatomical characters of peritonitis, pleuritis, and pericarditis are not unfrequently present, the inflammation, however, of these membranes being probably dependent on a prior affection of the solid viscera which they invest, viz., the lungs, heart, liver, spleen, and kidneys. Circumscribed softening of the brain is sometimes observed. Fibrinous clots of ante-mortem formation are often found in the right cavities of the heart.

The lesions just enumerated are, in great measure, those already noticed as incident to embolism (*vide* page 71, *et seq.*). Now, does this fact prove that pyæmia is neither more nor less than embolism? A negative answer to this question is based on the following considerations: Cases of embolism by no means always present the clinical history of pyæmia. The so-called infarctions occur in different viscera without the constitutional symptoms which are considered as denoting a purulent infection of the blood. In cases of pyæmia, the constitutional symptoms—pulse, temperature, etc.—are out of proportion to the local effects, that is, the multiple abscesses, etc., and life may be destroyed apparently as a direct consequence of the blood-poisoning irrespective of these local effects, although, doubtless, the latter react upon the system and give rise to more or less increase of constitutional disturbance. In some well-marked cases of pyæmia these local effects are wanting. Certain of the local secondary affections are not explained by the theory of embolism; for example, the inflammation within the joints and the extensive subcutaneous abscesses. Lesions which, it is admitted, involve embolism, seem often to involve something more than

the effects of simple obstruction of the vessels. This statement applies to active inflammation and sloughing in the lungs and elsewhere. It appears to be a fair conclusion from these considerations that, although embolism forms an important element in many, if not most, cases of pyæmia, the morbid condition of the blood denoted by the latter term embraces something more than the presence of either plugs or disintegrated thrombi, which produce their local morbid effects by a mechanical obstruction of arteries. Pure embolism is not properly a toxæmia, whereas the phenomena of pyæmia point to an extremely grave toxæmic condition.

The evidence that in pyæmia there is a purulent infection of the blood is derived from the following facts: The affection occurs connectively to suppurative inflammation. It occurs when, from the situation of the suppuration, as in osteo-myelitis, it is apparent that pus is liable to enter the circulation. The phenomena may be produced by injections of pus into the veins in inferior animals. The experiments of Savory, it may be here stated, show that even the local effects of embolism in the lungs, that is, multiple abscesses and gangrene, may be produced by the injection of pus serum, filtered so as to exclude all solid particles which might act as capillary emboli.[1]

Embolism, occurring in pyæmia, is doubtless dependent on thrombosis of veins, either within, or in the neighborhood of, the parts affected with suppurative inflammation. Phlebitis, whether it be a cause or an effect, of thrombosis, doubtless occurs in a certain proportion of cases. The emboli, under these circumstances, may become the carriers of a special toxic principle. In addition, the pus in mass, or the liquor puris, may gain entrance into the blood, either through open orifices into veins or by absorption. In what consists the special morbific agency of pus in cases of pyæmia, whether this agency be due to chemical changes or to the presence of animal or vegetable organisms, are points of inquiry which further researches are to elucidate.

The question as to the contagiousness of pyæmia is, of course, one of not only pathological interest, but practical importance. With reference to this question, the view which seems most rational is, that emanations from suppurating parts contain a materies morbi which, by coming into contact with existing wounds or external inflammations, and exciting therein a morbid action, leads to pyæmia. According to this view, pyæmia is not communicated, like smallpox, typhus, etc., by an infectious miasm entering into the system through the lungs or the alimentary canal; but it is, nevertheless, communicated by means of a virulent morbid product acting primarily on a part already suppurative. This morbid product diffused in the atmosphere, attached to the walls of hospital wards, to bedding, the clothing of medical attendants, etc., occasions the production of the disease in those suffering from wounds, or after surgical operations. Hence, the importance of ventilation, the efficient use of disinfectants, and the isolation of cases treated in hospitals.

Septicæmia.—This term denotes the presence in the blood of septic matter, that is, a product of the putrefaction of animal substance. The term is synonymous with "putrid infection of the blood." Putrescent matter is supposed to enter the blood either through the lymphatics or the veins, in certain cases, after wounds and surgical operations. Typical examples are afforded by these cases, and, moreover, they form the great

[1] *Vide* articles by William S. Savory in St. Bartholomew's Hospital Reports, vol. 1, 1865: also vol. 3, 1867.

majority of the cases of septicæmia. Hence, this morbid condition belongs rather to surgical than to medical pathology. The absorption of putrid matter from within the uterus is supposed to take place sometimes after parturition, especially if portions of the placenta be retained. A certain proportion of the cases of so-called puerperal fever, thus, are cases of septicæmia. This morbid condition of the blood may also be produced by the absorption of putrid matter from situations in which spontaneous, that is, non-traumatic, sloughing, or gangrene occurs.

Clinically, the symptoms which are recognized as characterizing septicæmia, present certain features, by means of which it may be differentiated from pyæmia. With or without an initial chill, fever occurs, and the thermometer indicates speedily a considerable rise of temperature. There is no recurrence of chill, if it have once occurred, but perspirations early in the disease are not infrequent. Diarrhœa is generally present, and it is often profuse. Delirium often occurs, which may be manifested by incoherence and muttering, or sometimes by mania. Aside from delirium, somnolency and indifference are mental symptoms commonly present. Generally before death the extremities become cold, and the thermometer shows a decline of temperature which sometimes falls below the minimum of health. It is supposed that septic poisoning, in a mild or moderate degree, not infrequently occurs and ends in recovery; but in the cases in which the symptoms denote a grave affection, the proportion ending fatally is very large. The duration in fatal cases is short, in general only a few days, but it is sometimes prolonged to several weeks.

As regards the appearances after death, the infarctions attributable generally to embolism, and the multiple abscesses so often found after death from pyæmia, are wanting. Evidence of pleuritis and pericarditis is sometimes found. The spleen is enlarged and softened. Suppuration beneath the skin and gangrene are, in some cases, secondary affections. The intestinal mucous membrane is often swollen and softened.

The evidence of the existence of a putrid infection of the blood is derived from, 1st, the occurrence of a group of symptoms, forming a well-defined and recognizable acute general disease which is developed in connection with putrefactive decomposition incident to wounds, surgical operations, parturition, and spontaneous gangrene; and, 2d, the similarity of symptoms and appearances after death, when putrid liquids are injected into the veins of inferior animals.

If it be true, as is now held by many, that putrefaction always involves the agency of minute organisms, then, of course, it follows that the causation of septicæmia involves the presence of these organisms. This view of the causation will account for the efficacy of disinfecting agencies and topical applications which are destructive to infusorial life; and this view enforces the importance of preventing the access of putrescent germs contained in the atmosphere to parts which are the seat of traumatic or idiopathic inflammation, and, if this cannot be done, of employing carbolic acid or other means of effecting their destruction. It is affirmed by L. Coze and V. Feltz, that the organisms known as bacteria are found in the blood in abundance in cases of septicæmia, and that herein consists an essential pathological distinction between this affection and pyæmia, these organisms not being found in the latter affection.[1]

Although there are sufficient grounds for considering pyæmia and

[1] Recherches cliniques et experimentales sur les maladies infectieuses etudiées spécialment au point de vue de l'état du sang et de la presence des ferments. Paris, 1872.

septicæmia as distinct toxhæmic conditions, yet clinical observation shows that the phenomena of both may be combined. After wounds, surgical operations, and parturition, as well as in connection with sloughing or grangrene when not produced by traumatic causes, in some cases, both putrid and purulent infection of the blood ensue, the symptoms and the morbid appearances belonging to each being associated.

Melanæmia.

Microscopical observers within late years have described a morbid condition of the blood consisting of the presence, in more or less abundance, of pigmentary granules and dark-colored cells. The granules are black or brown particles, rounded or angular in form, existing in the blood isolated and collected in masses. The cells resemble the white globules of the blood in form and size, their dark color being due to the pigmentary granules which they contain. Robin considers them to be the white globules, or leucocytes, containing dark-colored granules. To this morbid condition the name melanæmia has been applied.

Melanæmia is observed both after death and in blood drawn during life, in cases of malarious disease. Certain organs of the body, in examinations after death, in cases of periodical or malarial fever, present notable discoloration from an accumulation in the capillary vessels of pigmentary granules and the dark cells. The liver and the spleen are the organs in which this discoloration is especially observed, but it may extend to the brain, spinal cord, kidneys, lungs, and other parts.

The pathological effects of the melanæmic condition cannot be considered as established. Frerichs supposes that the accumulation of the granules and cells in different organs may occasion obstruction to the circulation sufficient to give rise to congestion and stasis, and to interfere materially with the functions of the organs affected. The accumulation of pigment in the liver, he thinks, may explain, in some cases, the occurrence of intestinal hemorrhage, diarrhœa, and dropsical effusion into the peritoneal cavity. Cerebral phenomena—stupor, delirium, convulsions, or paralysis —may possibly be due to the accumulation of pigment in the brain ; and the accumulation in the kidneys may cause albuminuria and general dropsy. The production of anæmia is attributed by Frerich to the accumulation of pigment in the spleen.

The source of the pigment is supposed to be the hematin or coloring matter of the blood ; hence, melanæmia involves destruction and consequent paucity of the red globules, or anæmia. Virchow supposes that the pigmentary granules and the cells are derived from the spleen, and, hence, melanæmia is a result of disease of that organ. The melanæmic condition will be referred to in connection with the morbid appearances found after death from malarial fever, in the second part of this work.

Viruses—Miasms—Venoms—Poisons.

Of the morbid conditions of the blood induced by morbid products originating within the bodies of the persons affected, that is, intrinsic products, there are doubtless many in addition to those which have been noticed. We do not possess demonstrative nor even inferential knowledge of the different kinds of these morbid products existing in the blood, the sources whence they are derived, the manner of production, etc. We only know, by means of clinical observation, some of the circumstances under which they originate, and the phenomena to which they give rise. They

belong to what may be called the indeterminate morbid conditions of the blood. Deferring, for the present, the consideration of these, the morbid conditions of the blood induced by morbid products derived from other bodies, and those induced by extrinsic matters other than morbid products, claim attention. Morbific substances, of various kinds, developed exterior to the body, *i. e.*, extrinsic, may gain access to the blood, and give rise to disease, either directly, by their immediate action on one or more parts to which they are transported in the blood, or indirectly, by occasioning morbid changes in the blood itself.

In this category are embraced morbid products by means of which certain diseases are communicated from those affected with them to others in health. These diseases are called either contagious or infectious. The morbid product which is the efficient agent in the communication of a contagious or an infectious disease is called a *virus*. A virus is a morbific principle, produced in the body of a patient having a particular disease, which is capable of producing the same disease when it enters the blood of another person. As thus defined, a virus is sometimes contained in matter which is appreciable, and this matter may be either liquid or solid. Examples are the fluid contents of a variolous vesicle, and the crust or scab which is formed by desiccation—both contain a morbific principle which is capable of producing smallpox. In this disease there are emanations from the body, not apparent to the senses, which contain, also, the virus, inasmuch as, getting into the blood, probably through the inspired atmosphere, they are capable of communicating the disease. The insensible emanations from the body belong among the morbific matters distinguished as *miasms*. A miasm may be defined to be morbific matter not recognizable by the senses. This term, however, is not limited to emanations from the body; all inappreciable forms of morbific matter may be called miasms. Of course, then, there are miasms which do not contain a virus, since a virus is always a product of disease. A familiar example of a miasm of this kind is the malaria which causes periodical fever, or marsh miasm, as it has been called.

In this connection the terms contagion and infection may be defined. These terms have been, and still are, used without much precision as regards the relative signification of each. They are often used as synonyms. The definitions of different writers do not agree. It is not easy to settle upon definitions which are in all respects satisfactory. The term contagion, in its etymology, implies communication of a disease by contact. If, however, the sense of the term be extended by considering that the contact may be immediate or mediate, it may embrace all modes of communicability, including emanations, the medium of contact, in the latter, being the atmosphere. If it be desirable to give a precise definition to each term, *contagion* may be restricted to the communication of a disease by means of a virus contained in a palpable morbid product, viz., serum, lymph, pus, or solid matter. On the other hand, *infection* may be used to denote communication by means of an inappreciable emanation or miasm. With this use of the terms, some diseases are propagated by contagion alone, for example, syphilis; some by both contagion and infection, for example, smallpox; and others by infection alone, for example, pertussis, or hooping-cough. It is, however, customary and convenient to treat of the diseases which are diffused exclusively by infection—scarlatina, typhus-fever, etc.—as contagious diseases. Moreover, the term infection is often applied to miasms which do not contain a virus.

Each contagious or infectious disease has its own peculiar and specific morbid product. The virus of smallpox, the miasm of scarlatina, for ex-

amples, produce respectively these two diseases, and no other form of disease. And in this fact we have a grand criterion of the special character of a disease, and of determining the identity or non-identity of diseases which may have more or less phenomena in common. Typhus and typhoid fever, for instance, have been considered by some identical, and by others non-identical. Now, when it is conclusively shown that the infectious miasm of typhus gives rise always to this form of disease, and never to typhoid fever, and, conversely, that the infectious miasm of typhoid fever gives rise to this disease, and never to typhus, we have the best of evidence that they are not one disease, but two distinct diseases.

Of the essential nature of the different morbific principles which constitute viruses, that is, in what consists their faculty of producing each its own disease, and of reproducing the same virus, we have not, as yet, positive knowledge. The hypothesis which has of late years been generally entertained—an old doctrine revived by Liebig—is, that a virus, received into the blood, acts as a ferment, exciting therein processes called catalytic. The grounds for this hypothesis are the inappreciable amount of material substance which suffices to communicate a disease, and the occurrence of days or weeks between its introduction into the blood and the manifestation of any morbid phenomena. Diseases supposed to be thus produced have been distinguished as *zymotic*, a term denoting a ferment, which was introduced and made the basis of a nosological arrangement of diseases by Farr. All contagious or infectious diseases were considered as zymotic, and also all diseases which prevail as either epidemics or endemics. For information respecting the processes embraced under the vague term catalysis—a term which has served chiefly to mask our ignorance of the nature of the processes which it embraces—the reader is referred to other works. Suffice it to say, with regard to fermentations, it seems to be well established that they are not mere chemical reactions excited by the presence of what is known as the ferment; but they are effects of the functional activity of living organisms, either animal or vegetable. At the present moment it is a question whether the doctrine of zymosis be not, in a great measure, resolvable into what is now known as the germ theory of disease. According to this theory, in certain diseases, morbid fermentative or catalytic processes take place without any reproduction of a materies morbi, that is, a virus capable of developing the disease in others. These processes may be compared to the action of diastase, which, placed in a solution of starch, changes the starch into glucose; but the resulting compound has no power to effect the same change in another solution of starch. The so-called zymotic diseases to which this analogy is applicable, not giving rise to a contagious or infectious virus, are not communicable. On the other hand, certain diseases involve in their causation and pathology fermentations in which the ferment, that is, the virus, is reproduced. A comparison applicable to these diseases is the alcoholic fermentation, the power of inducing the same process being transmitted to the yeast through successive generations. The diseases characterized by fermentations of the latter kind are contagious or infectious. Further notice of this theory will be made at the end of the next chapter in connection with the causation of diseases.

An extrinsic morbid product, giving rise to a morbid condition of the blood, may come from an inferior animal. Hydrophobia is thus derived from the dog or cat, and glanders from the horse. Disease in man may, also, be produced by the introduction into the blood of a healthy product of secretion derived from an inferior animal. Such a product is not a virus, but a *venom*. Venomous animals produce, physiologically, a pro-

duct which, received into the system of man, or another animal, gives rise to disease. Thus, certain serpents and insects have special glands furnishing secretions which cause disease and even death when introduced in sufficient quantity into the human body. These secretions, normal as regards the animals which furnish them, are venomous.

Various morbific substances which are neither viruses nor venoms are embraced under the name poisons. They are derived from the mineral and the vegetable kingdom. Their morbid effects are, in general, proportionate to the quantity of poison received into the system. Here is a striking point of difference as contrasted with viruses. The morbid effects of the latter bear little or no proportion to the amount received. The effects of some poisons are cumulative; that is, they are manifested suddenly, as it were, by a kind of explosion, when the quantity has increased to a certain amount. Lead, for example, may be taken into the system for a long period without any manifestation of morbid effects, but at length, when the accumulation has reached a certain point, its poisonous results are suddenly declared.

Extrinsic poisons are palpable and impalpable. Palpable poisons admit of examination, and their source and nature are understood, but not always the mode of their operation. Impalpable poisons belong among the miasms. The physical and chemical characters of these have not been ascertained, and their sources are not always known.

The palpable poisons are numerous. Their study constitutes an important branch of scientific inquiry, called *Toxicology*. Examples of the palpable poisons are, arsenic, lead, mercury, prussic acid, etc. etc. It is now generally admitted that they act by getting into the blood, and not by means of sympathetic influences propagated from the part with which they first come into contact, as was formerly supposed. They offer marked differences as regards the gravity of their effects. Some are quickly fatal in a small quantity, as prussic acid, strychnia, aconite, etc. Others act more slowly and with less virulence, as mercury, lead, etc.

The effects of extrinsic poisons are manifested in different parts of the body. Certain poisons exert effects on particular parts. Thus, alcohol and opium exert their effects on the brain, arsenic and oxalic acid on the heart, strychnia, woorara, and conia on the spinal cord, mercury on the mouth, lead on the muscles, etc. Many, however, act simultaneously on a greater or less number of parts. As regards their effects on the blood, some are merely mixed, or in solution, and act directly on parts to which they are carried in the circulation. Oxalic acid, arsenic, mercury, lead, prussic acid, alcohol, etc., have been discovered in the blood. In other instances chemical combinations take place in the blood. A striking illustration of this is afforded by one of the experiments of Bernard. Emulsin and amygdalin are not poisonous separately, but they combine and form prussic acid. Injected separately into the veins in different animals, they do no harm. If, however, they are successively injected into the veins of the same animal, they combine in the blood to form prussic acid, and the animal dies as if struck by lightning. On the other hand, the blood prevents certain combinations which take place readily out of the body. An experiment of Bernard illustrates this fact. Cyanuret of potassium and lactate of iron in combination form Prussian blue. Injected successively in the veins, they do not combine in the blood, but the combination takes place and Prussian blue is formed after both have entered the urine, or within the intestinal canal.

Examples of impalpable poisons are the miasms giving rise to the periodical fevers, epidemic cholera, cholera infantum, epidemic dysentery, yel-

low fever, etc. All the extrinsic causes of disease which are special in their character, and not of the nature of virus or venom, belong among the miasms. By the term special is meant causes, each of which produces exclusively a particular disease. Now, the existence of a special cause, as just defined, may be inferred from the special character of a disease. Whenever, therefore, the special character of a disease is established, we may attribute it to a toxical origin. All endemic and epidemic diseases have a special character; in other words, the events which make up their clinical history are so definite and are regulated by such fixed laws, that they undoubtedly proceed from special causes, which it is certain are produced, not within, but without, the body. These special causes are not of the nature of virus or venom; they are impalpable, or miasms. But their nature and source are very imperfectly known, nor does our present knowledge enable us to understand the morbid conditions of the blood which they occasion. Of course, these morbid conditions and the special causes differ in different epidemic or endemic diseases. The condition and the cause in yellow fever, for example, cannot be the same as in epidemic cholera, in view of the differences as regards the phenomena and laws between these two diseases. But there is this striking point of contrast between the operations of poisonous miasms and the virus of contagion and infection: Poisonous miasms do not lead to a reproduction, by the processes of disease, of the poison, and, hence, the diseases to which they give rise are not communicable.

Indeterminate Blood-Changes.

The morbid conditions of the blood, so far as they are at present known to the pathologist, have now been passed in review. It is evident that our existing knowledge is very incomplete. Were all the morbid conditions of the blood fully understood, there is reason to believe that we should have a thread guiding us far through the labyrinth of pathology. This knowledge would probably do much toward elucidating the greater part of the morbid conditions of the solid structures. The most rational view of the source of disorders referable to the circulation, to the various secretions and excretions, nutrition, together with morbid states of the muscular and nervous systems, is, that they proceed often, if not generally, from blood-changes. The blood offers at the present moment a most interesting and promising field for the scientific inquirer. It is here that important discoveries are to be made which will shed light on the nature and source of diseases now imperfectly understood. In view of the physiological relations of the blood, and what has been already ascertained respecting its pathological relations, it is safe to prophesy that future revelations in pathology are mainly to come from analytical, microscopical, and experimental researches in this direction.

The remark has been already made that the existence of numerous morbid conditions of the blood may be logically inferred, although, with our present knowledge, they cannot be demonstrated. In other words, there are many *indeterminate blood-changes* involved in different diseases. What are the considerations which warrant this conclusion? I shall devote the remainder of this chapter to the answer of this question.

It is a reasonable supposition that all the diseases distinguished as *general*, or *constitutional*, or *of uncertain seat*, involve blood-changes. In fevers, generally, if not always, these changes are occasioned by extrinsic morbific matter, either a virus, a miasm, or a poison. But many other diseases evidently involve a general or constitutional pathological condition,

called a cachexia or dyscrasia. Now, it is more rational to refer this condition to the blood than to any other portion of the body. Exclusive of the blood, there is only one anatomical system sufficiently extensive in its relations to warrant a suspicion of its being the seat of the essential pathological condition in general or constitutional affections; this is the nervous system. But the nervous system, as a generator of force, depends on the blood. Without blood it develops nothing, and its functions are soon lost. Morbid conditions of the blood voluntarily produced affect powerfully the nervous system. For examples, alcohol injected into the veins produces the phenomena of inebriation, chloroform or ether extinguishes sensation, strychnia excites the motor fibres of the spinal cord, woorara paralyzes them, etc. These substances exert their effects either by being transported in the blood and acting upon the organs affected, or by means of modifications which they produce in the blood. Clinical observation, moreover, shows that a large proportion of nervous affections are due to prior blood-changes. As between the blood and nervous system, therefore, the essential pathological conditions which constitute the cachexiæ or dyscrasiæ must relate primarily to the former.

Assuming the correctness of the statement just made, it is enough, with regard to any local affection, to show that it is dependent on a general or constitutional morbid condition, in other words, that it involves a cachexia or dyscrasia, to render it probable that it proceeds from a blood-change of some kind. It only remains then to inquire what circumstances authorize the inference that a local affection depends on a general or constitutional condition. The following are grounds for such an inference:—

1. A local affection not due to the action of an appreciable cause acting on the part affected, is said to be spontaneous. Of course, it is not so called with strict propriety. Every affection must have an adequate determining cause. The distinction implied by the term is, the cause is internal and inappreciable, and the term is used in contradistinction from causes called traumatic. Now, the internal determining causes involved in the production of the so-called spontaneous diseases, it is not probable, are exclusively local; they are not generated within the parts affected, but, originating within the system somewhere, they are brought to bear upon the organs or structures in some particular situation. For example, a person, exposed to no obvious cause of disease, is attacked with pleuritis; whence comes the internal cause determining this disease? It is reasonable to conclude that the disease is a local expression of some prior more general morbid condition. Clinical researches have shown this to be true in certain cases in which pleuritis, occurring in the course of Bright's disease, is fairly attributable to the accumulation of urea in the blood. The so-called spontaneity of any disease is presumptive evidence of its being a result of the localization of a morbid condition seated in a movable element of the body, that is, the blood. Going no further than the simple fact of a local affection developed without any appreciable local cause, the existence of a blood-change is a logical inference from this fact. That most local affections distinguished as spontaneous do proceed from some general or constitutional morbid condition, is rendered probable, in addition to the consideration just presented, by others which are to follow.

2. Local affections characterized by morbid deposits are, from this fact, rationally attributable to a morbid condition of the blood. The production, for example, of purulent matter in great abundance, having the property of virus in smallpox, or the morbid product within the Peyerian, solitary, and mesenteric glands in typhoid fever, denotes a blood-change proper to each of these diseases. In like manner, all the cutaneous erup-

tions involving morbid products, especially when not due to obvious local causes, in other words, when spontaneous, imply blood-changes. The old medical philosophers, guided by common sense, before the discovery of the circulation, attributed most diseases to the presence of certain *peccant humors*, which were to be concocted and expelled before recovery could take place. They regarded the local and general phenomena of diseases as proceeding from the efforts of nature at coction and elimination. Morbid processes, therefore, were, in a great measure, conservative. These notions gave way under the influence of an exclusive solidism, developed and fostered by the study of morbid anatomy which is occupied, not with morbid actions, but their results; disease itself was overlooked, the attention being engrossed with its effects. But in the ancient common-sense notions lies the germ of true pathology, as modern researches are constantly exemplifying more and more. With our present knowledge, the old humoral doctrine is, in the main, applicable to the diseases which have been named; and its application may be extended to other diseases characterized by morbid deposits, such as gout, tuberculosis, carcinoma, and perhaps even to certain inflammations attended by the exudation of lymph.

3. Disorders of the different secretions and excretions denote blood-changes. This is true more especially of excretions, inasmuch as excreted matters exist formed in the blood, and are simply eliminated by the excretory organs.

4. The fact of local affections occurring simultaneously or in quick succession in different situations, is evidence of a general or constitutional morbid condition. Examples are, multiple abscesses in so-called pyæmia, tubercle deposited in various organs, cancer, etc. Shifting of the location of the manifestations of disease, as in acute articular rheumatism, is an-another point of evidence.

5. The occurrence of a local affection on the two lateral sides of the body, and a correspondence of the affection of the two sides as regards the character of the affection, its situation, extent, etc., constitute a very strong point in evidence of a constitutional morbid condition, involving a blood-change. A striking law of symmetry characterizes certain diseases. They may be distinguished as symmetrical diseases. Examples are various cutaneous diseases, articular rheumatism, Bright's disease of the kidneys, pulmonary tuberculosis, etc. We cannot well conceive that the internal determining conditions which give rise to the local manifestations in these diseases are seated elsewhere than in the blood. We may assume it to be a rational conclusion that the essential pathology of all symmetrical diseases pertains to the blood; and the fact that the law of symmetry is exemplified in any disease, suffices to render it probable that it is a blood-disease.

6. The *modus operandi*, so far as known, of remedies found to be useful in the treatment of a great number of local affections, shows their source to be in the blood. The remedies referred to are those which act by being absorbed into and modifying the blood. These remedies have been significantly termed *alteratives*. Their immediate effects in the blood are unknown; we can only say that they alter in some way and affect sensibly the condition of the blood. Examples are mercury and iodine.

The foregoing are some of the considerations which establish, by logical inference, the general or constitutional origin of local affections, the nature of the general or constitutional morbid condition being unknown, but consisting, as is rationally probable, in indeterminate pathological changes in the blood. Other considerations which might be adduced are omitted, the aim being, not to enter into a discussion of this topic, but only to furnish suggestions for the inquiries and reflections of the reader.

The general doctrine that the primary morbid conditions in most diseases are seated in the fluids, distinguishes what has been called the *humoral pathology*, in contradistinction from *solidism*, the doctrine expressed by the latter term being that diseases originate in the solid parts or tissues. The view which has just been presented respecting the great extent to which blood-changes are involved in disease, does not require the belief that these changes are necessarily humoral in their origin. There is ground for the belief that many, if not most, of the morbid changes of the blood are secondary to, and dependent upon, local morbid processes in solid parts. When the physiological changes in the blood are considered—several pounds of fresh material being daily added and an equal amount parted with in the processes of exhalation, secretion, excretion, and nutrition—it is difficult to conceive how definite morbid conditions here can be self-persisting, that is, continue from the operation of laws inherent in, and limited to the blood. Moreover, it is to be considered that the blood in health is not self-existing and self-renewing, but that it is dependent upon the action of solid organs. The indeterminate blood-changes which constitute the essential pathological conditions in the different cachexiæ or dyscrasiæ, may not originate in the blood, but may owe their origin to the continued introduction into the blood of noxious matter derived from local sources, or to effects of some kind produced by certain organs.[1] In the existing state of our knowledge, the doctrine that diseases are primarily humoral, is no more to be inculcated than the doctrine of exclusive solidism; but, appreciating the limits of our knowledge, the mind should be prepared to accept the development or establishment of truth without being biased by an attachment to either doctrine.

CHAPTER VIII.

THE CAUSES OF DISEASE, OR ETIOLOGY.

Etiology a branch of General and Special Pathology—Its importance—Internal or Intrinsic and External or Extrinsic Causes—Ordinary, and Special or Specific Causes—Traumatic Causes—Spontaneous Diseases—Primary and Secondary Causes—Complications and Intercurrent Diseases—Predisposing and Exciting Causes—Congenital and Inherited Predispositions to Disease—Co-operating Causes—Diathesis—Cachexia or Dyscrasia—Endemic Diseases dependent on Emanations from the Soil—Epidemic Diseases produced by Causes existing in the Atmosphere—The Causes of some Contagious Diseases exclusively derived from those affected with these Diseases, and other Diseases of this class produced, in some cases, by other Causes than Contagion or Infection—Fomites—Portability of the special Causes and Diseases not Contagious nor Infectious.—The Causes of Contagious and Infectious Diseases probably Living Germs or Organisms.

ETIOLOGY is that branch of medicine which treats of the causes of disease. As one of the divisions of the Principles of Medicine, or General Pathology, it treats of causes considered with reference, not to individual affections, but to disease in general or in different groups of diseases. The consideration of the causes of individual diseases forms

[1] *Vide* Virchow's Cellular Pathology, Lecture VI.

an important part of special pathology, or the practice of medicine. Etiology, therefore, enters into the range of topics belonging to the first and second parts of the work. Following the general plan pursued in the foregoing chapters, I shall limit myself here to certain distinctions and definitions which are to be understood as preliminary to entering on the study of individual diseases.

Knowledge of the causes of disease is highly important, in a practical view, as the basis of prophylaxis, or the prevention of disease. It is obvious that in proportion as we are able to trace diseases to their sources, we may expect to extinguish causes or obviate their morbific influence. Knowledge of causes also is important as entering into the management of diseases; for it not unfrequently happens that causes continue to be operative after disease has been produced, and their removal is, of course, a prime object in order to effect a cure. It will be apparent, when we come to inquire into the causes of individual diseases, that the amount of our present knowledge in this direction is extremely limited. It is true that modern researches have developed much information, and not a little progress has been made in the prevention of diseases in consequence of increased knowledge of etiology, but there yet remains a wide field for further developments.

In treating of morbid conditions of the blood, reference has been made to certain causes of disease originating within the bodies of persons affected, and to other causes which are received from without. Here is one ground of distinction. Causes are *intrinsic* or *internal*, and *extrinsic* or *external*. Examples of external or extrinsic causes are the different kinds of miasm, infectious or poisonous, the various species of virus, venous, palpable poisons, together with the numerous agencies of disease by means of wounds or injuries. On the other hand, examples of internal and intrinsic causes are, an accumulation of urea in the blood, an excess of uric acid in gout, a morbific principle in rheumatism supposed to be lactic acid, etc.

Among the internal causes belong those which originate in the mind; and these play an important part in the production of morbid phenomena. Over-exertion of the faculties of the mind, mental application unduly prolonged, and intense or long-continued emotional excitement, lead to disorders of the nervous system, together with more or less impairment of the vital forces. Insanity and minor forms of mental derangement may not unfrequently be traced to these causes. The bodily functions are weakened, partly from direct influences pertaining to the nervous system; and, in part, because the operation of these causes involves neglect of hygienic conditions of health which relate to diet, muscular exercise, recreation, etc. Long-continued mental depression, whether produced by the causes just named, or other causes, often stands in a causative relation to disorders of digestion and anæmia. An absorbing sentiment or passion may induce disorders by leading to neglect of the means of preserving health. Finally, a concentration of the attention on the bodily functions, over-anxiety concerning health, and a craving for the interest or sympathy which illness is expected to awaken in others, are important elements entering into many cases of disease, especially among females. The knowledge and tact of the physician are often called into requisition in estimating the agency of these various causes referable to the mind.

Causes may be distinguished as *ordinary*, and *special* or *specific*. Ordinary causes are those to which all persons are more or less exposed, and which may give rise to two or more forms of disease. Atmospherical vicissitudes are ordinary causes. They are generally supposed to be involved in the causation of disease very frequently, and to give rise to a

great variety of diseases. Special or specific causes are extraordinary in their occurrence, that is, persons are exposed to them only at certain times or in certain situations, and each cause gives rise uniformly to one particular form of disease. The poisonous miasm which produces periodical fever, the infectious miasm which causes typhus, the virus which gives rise to smallpox, etc., are examples of special or specific causes. The miasm which produces periodical fever is not capable of producing typhus, the infection producing typhus will never give rise to periodical fever, and the same is true of all other causes belonging in this category. The existence of a special or specific cause may be inferred from the specific character of a disease, although the nature and source of the causative agent are not understood. It is certain, for instance, that diseases possessing phenomena and laws so distinctive and uniform as those which belong to the clinical history of epidemic cholera, typhoid fever, yellow fever, etc., must each have its own special or specific cause, although the causes of these diseases have thus far eluded investigation.

Certain causes are distinguished as *traumatic;* and this name is applied also to distinguish the diseases produced by this class of causes. Traumatic causes are those which give rise to disease by acting in an appreciable manner on the part affected. Traumatic diseases are those thus produced. Anything which occasions an injury or wound of a part, and consequently disease of that part, is a traumatic cause. The name signifies a wound. A bronchitis caused by the inhalation of an irritating vapor is produced traumatically. A calculus in the pelvis of the kidney which gives rise to pyelitis, and a stone in the bladder which occasions cystitis, are traumatic causes. The causes thus distinguished, therefore, may be either internal or external, although, in the great majority of cases, they belong to the latter class.

Diseases not traumatic, and which do not proceed from any appreciable causative agency, are said to be *spontaneous*. This term, as thus applied, is to be taken in a conventional, not a literal sense. It is obviously incorrect to say of any disease that it originated spontaneously. Every disease must have its adequate determining cause. But many diseases are developed without our being able, in the existing state of knowledge, to refer them to their causes; and the term spontaneous, applied to those diseases, means simply that they proceed from causes which our present knowledge does not enable us to appreciate. Pleuritis, pericarditis, and other affections developed frequently in the course of Bright's disease, were formerly considered as spontaneous; but now that their development is attributable to the action of urea accumulating in the blood, the term has ceased to be applicable to them. The number of so-called spontaneous diseases will diminish in proportion as our knowledge of etiology advances.

Causes are distinguished as *primary* and *secondary*. A secondary cause is an effect of disease. Urea, for example, accumulating in the blood, gives rise to various local affections—pleuritis, pericarditis, etc. But the accumulation of urea is an effect of some disease of the kidneys, which interrupts the eliminative function of these organs. Urea in excess in the blood, is thus a secondary cause of disease. A primary cause, on the other hand, does not proceed from a prior disease. All external traumatic causes, for instance, are primary. The same distinction is made among diseases; that is, some are primary, and others secondary.[1] Primary diseases proceed from primary causes, and those called secondary

[1] Protopathic and deuteropathic.

are due to the effects of pre-existing diseases; in other words, to secondary causes. A large proportion of the diseases, the existence of which is first ascertained, are secondary; they involve in their causation antecedent affections. Not unfrequently a number of diseases are thus linked together in a consecutive series. In the examination of patients, therefore, it is not sufficient to have discovered a disease; but, having discovered one disease, it remains to be ascertained whether one or more additional diseases do not exist, sustaining to the disease first discovered a relation either of cause or effect. Clinical researches have developed important facts with respect to the causative relations existing between different diseases, and these facts are of great utility in medical practice.

Secondary and subordinate affections are distinguished as *complications*. A complicating disease is one which occurs in the course of another disease with which it is connected by some pathological relation. Pneumonitis, for example, developed in the course of typhoid or typhus fever, is a complication of the latter. It is consecutive to the fever, and to a greater or less extent dependent thereon for its production. Pneumonitis generally has a complication, viz., circumscribed pleurisy. A disease is said to be *intercurrent* when it occurs during the progress of another disease, without necessarily having any dependence on the latter. Lobar pneumonitis, for example, occurring in a patient affected with pulmonary tuberculosis, is an intercurrent affection.

As just stated, certain causes of disease are themselves effects of disease; so that certain diseases may be said to stand in a causative relation to other diseases. On the other hand, some diseases afford protection against others. As an illustration, emphysema of the lungs and pulmonary tuberculosis may be cited. The latter disease occurs in patients affected with the former so rarely as to show that it exerts a protective influence. Another illustration is afforded by disease of the heart and tuberculosis of the lungs. A tuberculous deposit occurs so rarely, when cardiac disease occasions much disturbance of the circulation, that the latter must be considered as affording more or less exemption from the former.

Another division is into *predisposing* and *exciting* causes. Predisposing causes induce a liability or tendency to certain forms of disease. Exciting causes, acting on persons already predisposed to certain diseases, determine their occurrence. Predisposing causes may be alone sufficient to give rise to disease, or they may only suffice to place the system in a condition favorable for the occurrence of disease; in the latter case, the disease occurs when exciting are superadded to the predisposing causes. To cite an instance: A person under the influence of predisposing causes is in a condition favorable for the occurrence of acute rheumatism; in this condition he is exposed to atmospherical vicissitudes, and the latter determine an attack of this disease. The exciting cause, viz., the atmospherical vicissitudes, would not, alone, have been adequate to give rise to an attack of rheumatism; and the former, viz., the predisposing causes, alone, might have been inadequate; but, conjointly, they occasion this disease. Exciting causes act the part of the match when everything is ready for an explosion. It is thus seen that predisposing causes determine the nature of the disease, and exciting causes the date of its occurrence.

A predisposition to some form of disease may be inherent in the constitution, or congenital. Some persons have inborn tendencies to certain diseases. This fact is strikingly illustrated by the occurrence of phthisis successively in different members of the same family—a large number of brothers and sisters being carried off by this disease. This congenital

predisposition may remain completely latent until the period of life in which the disease is most apt to be developed; and we sometimes see a whole family of children, one after the other, fall victims to this disease, when they severally reach a certain age. A predisposition to certain forms of disease may not only be congenital, but inherited; a constitution involving a tendency to disease is transmitted from parent to offspring. Among the diseases perpetuated in this way are phthisis, gout, cancer, asthma.

The predisposition to a disease, whether congenital or acquired, may be strong or feeble. Various circumstances may act as *co-operating causes;* that is, acting in furtherance of the constitutional tendency. Thus, in a person predisposed to phthisis, the development of this disease may be greatly promoted by unfavorable hygienic circumstances, such as sedentary habits, deficient ventilation, and inadequate alimentation. These co-operating causes, taken in conjunction with an existing predisposition, may serve to develop the disease, when, without their aid, the predisposition might not have been sufficient. There is reason to believe that persons with a feeble predisposition to this disease often escape, if they be exempt from the operation of co-operating causes. The latter, moreover, are to a greater or less extent controllable, while the predisposition, especially if it be congenital, is entirely beyond control. Diseases thus are preventable, notwithstanding a predisposition to them, in so far as they depend on the union of co-operating causes. Herein lies a truth of great practical importance.

Diseases which originate from special causes often appear to require for their production co-operating causes. Facts seem to show, for examples, that yellow fever, periodical fevers, and epidemic cholera, which undoubtedly involve the agency of special causes, would in many cases not have occurred, had not other than the special causes contributed to their occurrence. By eradicating, as far as possible, all unfavorable hygienic influences, the special causes of these diseases may be rendered, to a great extent, or perhaps completely, inoperative. The special causes of disease and the co-operating causes are, to quote the comparison of the late Dr. Barton, like the two blades of a pair of scissors—conjoined they may be effective, when disunited they effect nothing. The special causes of these diseases we may not be able to remove; but co-operating causes are, to a great extent, within our control; and, by removing the latter, the diseases are rendered preventable.

A constitutional predisposition to a particular form of disease constitutes what is called a *diathesis.* A diathesis, therefore, may be either congenital or acquired. And the diseases which are considered as generally, if not always, involving a constitutional predisposition, or diathesis, are sometimes distinguished as *diathetic* diseases. A *cachexia* or *dyscrasia* involves a diathesis, and something more. These terms denote, not merely a constitutional predisposition to disease, but that condition of the system which exists when the disease is actually developed. A person born with a tendency to phthisis, for example, has the tuberculous diathesis; and this diathesis eventuates in the tuberculous cachexia when the person becomes affected with phthisis.

Our present knowledge, for the most part, of the special or specific causes of disease, is based on inference rather than on demonstration. But certain conclusions respecting their origin and diffusion may be logically determined. One of these conclusions is, that some poisonous miasms emanate from the soil. This may be inferred with respect to the special causes giving rise to diseases called *endemic.* Endemic diseases are those

which prevail within circumscribed territorial limits; that is, their prevalence does not extend beyond sectional boundaries. Now, this fact is sufficient for the inference that the source of the causative miasms is in the soil; because, of the elements which enter into climatic influences, those peculiar to any particular district are terrestrial. Again, in the diseases called *epidemic*, viz., those which prevail successively or simultaneously in different and often wide-spread territorial districts, the poisonous miasms, whatever may be their source, must be diffused through the atmosphere. The causes of epidemic disease are migratory. In some instances they traverse successively almost every portion of the habitable globe. This is true of epidemic bronchitis or influenza, and of epidemic cholera. It is altogether improbable that the special causes in these and other epidemics are developed in the different sections of country over which their prevalence extends. They are produced in the situation whence they take their point of departure, and travel, in some way, through the atmosphere. The special causes which give rise to contagious and infectious diseases are derived from the bodies of those affected with these diseases; and, with respect to certain of these diseases, it is probable that the special causes are exclusively thus derived. It may fairly be doubted whether smallpox ever originates from any other source, notwithstanding the occurrence of cases in which it cannot be traced to contagion or infection. Yet, the first case of smallpox which ever existed must, of course, have been an exception to this law, and it is possible that there are still occasional exceptions. With respect to certain of the diseases which are communicable, it is probable that they not unfrequently originate otherwise than by contagion or infection. This is true of typhoid, and perhaps also of typhus fever.

Diseases are communicated, not only by viruses received by contact or diffused in the atmosphere, but by means of what are called *fomites*. This term is applied to any inanimate substances, such as clothing or articles of merchandise, to which contagious or infectious matter has adhered. In this way certain diseases, such as smallpox and scarlatina, may be disseminated at points far distant from the source of their special causes. The term fomites is restricted to the transmission of the matter of contagion or infection. But it is probable that other special causes of disease may be transmitted in the same way. Facts, for example, appear to show that the special cause of yellow fever is capable of transportation. And if this be true, it is correct to say that a disease may be *portable*, although not contagious nor infectious.

Special causes of disease, embraced under the names contagion and infection, have been noticed in giving some account of viruses (*vide* p. 97). As stated in that connection, the theory which seems most consistent with our present knowledge is, that the essential morbific principles (the contagium) in these causes, are living germs or organisms, either vegetable or animal. This is, by no means, a new theory. The doctrine that the source of epidemic diseases is in animalcule life was advocated many years ago (1839) by Sir Henry Holland, and in a volume by the late Professor J. K. Mitchell, of Philadelphia, published in 1847, were presented facts and cogent arguments in behalf of the cryptogomic origin of malarious and epidemic fevers. Indeed, the theory was advanced very early in the history of medicine, and in modern times was elaborately advocated by the great botanist, Linnæus. Very lately, however, the microscopical study of the lowest appreciable forms of life, and discussions relating to the long mooted question as to spontaneous or equivocal generation, have

led to the accumulation of weighty evidence in its support; so that the probability of its truth seems vastly greater now than hitherto.

Assuming the causes of contagious and infectious diseases to be living germs or organisms, a certain period is required for their development and multiplication within the body sufficiently to give rise to these diseases. In this way, better, perhaps, than in any other, may be explained the fact, that in contagious and infectious diseases, as well as in some which are not communicable, for a period which is sometimes extended to weeks, months, and even years, the special cause remains in the body completely latent as regards any morbid manifestations. The reproduction of germs and organisms within the body affords an intelligible explanation of the formation of viruses, or the morbific principles, by means of which, diseases are communicated. The self-limited duration of these diseases is explained by supposing that, after successive generations, the organisms die out, or they are in some way either destroyed or eliminated from the body. The germ theory affords a satisfactory explanation of another fact, namely, that an inappreciable quantity of virus suffices to give rise to the disease of which it is the special cause; and, moreover, that the intensity of the disease bears no proportion to the quantity of virus received. For example, the severest form of smallpox may follow the reception of an almost infinitessimal quantity of virus in infection, while, on the other hand, the disease may be mild after the utmost amount of exposure. In this point of view, these causes are in striking contrast with poisons, the effects of which are in proportion to the quantity received into the system.

A remarkable fact relating to the causes of contagious and infectious diseases is, that, as a rule, they exert their morbid effects but once in the same person. These diseases are rarely experienced a second time. Evidently this is because the susceptibility to the causes is destroyed, since it is not to be supposed that the latter lose their efficiency, and they undoubtedly are received into the system as readily after, as before, the disease had occurred. With our present knowledge, the mode in which the susceptibility to these causes is destroyed, cannot be explained. Assuming the causes to be germs, however, it is well known that the evolution and development of organisms therefrom require certain conditions. The seed must have its appropriate soil, and various circumstances may, on the one hand, promote, and, on the other hand, arrest its germination. In some inconceivable mode, contagious and infectious diseases effect a permanent destruction of the unknown conditions within the body, on which depend the development and multiplication of germs which, it is assumed, constitute the causes of these diseases. It should be added, that this is not exclusively an effect of diseases which are communicable. Yellow fever, for example, is rarely experienced a second time. A deficient susceptibility to the causes of contagious and infectious diseases is sometimes a natural defect. There are persons who, from birth, and during life, are in no degree affected by the virus of smallpox, and the same is true with respect to the causes of other diseases.

The demonstration of the germ theory requires, 1st, the proof afforded by direct observation of the existence of germs or organisms in the blood; 2d, that certain living forms are always present in connection with certain diseases; and 3d, that these forms are not to be found in the blood when the diseases do not exist. It is claimed by microscopical observers that these requirements have been fulfilled. The micrococci of Hallier, the microzymes of Béchamp, the bioplasts of Beale, and the several forms described by Salisbury are considered, by these observers, as characterizing

particular diseases. The studies of Davaine, Coze, and Feltz, and others appear to establish conclusively the fact that bacteria in certain diseases are found in the blood. As tending to prove that organisms may gain entrance into the blood from the alimentary canal, the experiments of Dr. Joseph G. Richardson, of Philadelphia, are especially interesting. They consisted in drinking putrescent liquids abounding in bacteria and vibriones, and afterward examining the blood at stated intervals, taking pains to prevent the introduction of infusoria into the specimens of blood after it had been drawn. These experiments showed the presence in the blood, within a short period after the ingestion of the liquid, of the same organisms contained in the latter; they showed that the number of bacteria and vibrios in the blood corresponded to the quantity of the liquid drank; that they disappeared from the blood after a certain number of hours, and that, introduced into blood after it had been drawn, they distinctly increased in size during a period of twenty-three hours.[1] To undertake to give even a condensed account of the varied experiments and observations relating to the germ theory, which are to be found in recent medical literature, would not only call for too much space, but it would be here out of place. Moreover, to judge of the accuracy of the microscopical observations, to endeavor to interpret facts, and to discuss the various questions connected with the theory—questions concerning the source of morbific germs; whether they are of animal or vegetable beings; the extent to which the organisms produced are dependent on the laws of development inherent in the germs, or on extrinsic circumstances; and, lastly, the long-mooted question as to spontaneous generation—to do all this, were there no difficulty on the score of space or propriety, qualifications are required to which I cannot lay claim.

In conclusion, the observations which have shown the great abundance and the wide diffusion in the atmosphere of organic entities invisible to the naked eye; the researches which seem to show that putrefactive and fermentative processes are effected by the agency of living organisms; the analogy, long recognized, between the phenomena of fermentation and those arising from certain of the unknown special causes of disease; the differences between the action of these unknown causes and of the known vegetable and mineral poisons; the discovery, by means of the microscope, within late years, of cryptogenic formations in affections of the skin and mucous membrane, and, also, of parasitic animals; the detection of living organisms in the blood and other liquids of the body; the successful employment—with a view to the prevention of diseases—of carbolic acid and other articles which are especially destructive to the lower forms of animal and vegetable life, and the apparent remedial power of some of these articles in certain of the so-called zymotic diseases—these are grounds for the conjecture, if not expectation, that continued investigations may lead to results which will greatly enlarge the boundaries of our present knowledge, not only in etiology, but in pathology and therapeutics.

CHAPTER IX.

SYMPTOMATOLOGY.

Pathognomonic Symptoms — Diagnostic Symptoms — Subjective and Objective Symptoms — Signs—Clinical History of Diseases and the different Modes by which it is obtained—Stages of Disease—Precursory or Prodromic Events—Sequels—Diagnosis—Reasoning by way of exclusion—Differential Diagnosis—Prognosis—Prognostics.

THE study of the symptoms of disease forms a division of the principles of medicine, or general pathology, called *Symptomatology* or *Semeiology*. The consideration of symptoms will occupy a large proportion of the space to be devoted to each individual disease, in treating of the practice of medicine, or special pathology, in the second part of this work. Continuing to pursue the plan adopted in the first part of this work, it will suffice to present in this chapter certain distinctions and definitions which should be understood before entering on the study of individual diseases.

The term symptoms embraces all the appreciable morbid phenomena occurring in connection with disease. The name signifies to fall together, and denotes concurrence of events. To reiterate the often quoted comparison by Galen, symptoms accompany diseases as the shadow follows the substance. By means of symptoms the existence of disease is made apparent, and the character and seat of different affections are ascertained.

Certain symptoms are distinguished as *pathognomonic*. A pathognomonic symptom is one which denotes invariably the existence of a particular disease. It derives this significance from the fact that it occurs only in connection with one disease. Whenever such a symptom, therefore, is present, it represents the disease, and, in itself, suffices for the recognition of the disease. The number of pathognomonic symptoms is quite small. As an illustration of the symptoms of this class, a semi-transparent, viscid, rusty-colored matter of expectoration belongs exclusively to pneumonitis. It is, therefore, a pathognomonic symptom, always denoting the existence of that disease. In like manner the crepitant râle, obtained by auscultation, is so distinctive of the same disease as to be nearly pathognomonic. It would be difficult to cite many examples in addition to the two just named.

A symptom is said to be *diagnostic* when it occurs more frequently in connection with a particular disease than with other diseases. Just in proportion as it is restricted to a few diseases, is its diagnostic character and importance marked; that is, it is of value as denoting the presence of some one of these diseases, and, therefore, of value in diagnosis. Different symptoms differ as regards their respective diagnostic value. Some are highly diagnostic; in other words, they point strongly to the existence of particular diseases. Others are moderately, and, again, others slightly diagnostic. The measure of diagnostic significance depends on the frequency of concurrence with a particular disease and the infrequency of concurrence with other diseases.

Symptoms are either *subjective* or *objective*. Subjective symptoms are those which relate to the sensations or feelings of the patient, and which,

consequently, the physician can appreciate only through the patient's description of them. Objective symptoms, on the other hand, are those which the physician observes for himself, and for a correct appreciation of which he is in no wise dependent on the patient. As regards subjective symptoms, the physician is exposed to error in consequence of inability on the part of the patient to describe them clearly. In young children this class of symptoms is not available. This is true, also, of idiots, the insane, and in the delirium incident to different diseases. As regards these symptoms, too, the physician is liable to be deceived by intentional misrepresentations on the part of patients; and he is liable to be deceived, unintentionally, by a tendency, on the one hand, to exaggeration, and, on the other hand, to depreciation of morbid sensations or feelings. Owing to these sources of error, much tact is often requisite in placing a proper estimate on subjective symptoms. Objective symptoms are not open to the same liabilities to error. The physician judges of these by the exercise of his own senses, and, if he fail to discover or place a proper estimate upon them, the fault consists in his own want of attention, judgment, or skill. Objective symptoms, thus, are much more reliable than subjective, in the investigation of cases of disease.

The exaggeration of pain or suffering of any kind, and of morbid sensations, is common, sometimes because patients are led to form an exaggerated idea of their subjective symptoms; sometimes with a view to awaken interest or sympathy; sometimes for malingering purposes, and sometimes to secure greater attention on the part of the physician with more efficient treatment. Factitious and exaggerated ailments enter pretty largely into the cases which the practitioner is called upon to treat, especially among females.

A symptom, as already defined, is any manifest morbid phenomenon or event. Occurring concurrently with a disease, it may, or may not, have a pathological connection with that disease. Its pathological connection with the disease may be such as to render it a pathognomonic symptom, or more or less diagnostic; and, on the other hand, it may be present as a mere coincidence, or accidentally. In the latter case, it has no pathological connection with the disease, and is devoid of diagnostic significance. This difference among symptoms has been expressed by calling them *signs* when they are either pathognomonic or more or less diagnostic. According to this distinction, a symptom becomes a sign whenever it denotes, in a greater or less degree, the existence of a particular disease. The term signs, however, has come conventionally to be used in a different sense. It is usual to apply this term to the phenomena obtained by certain methods of investigation distinguished as physical, viz., percussion, auscultation, etc. These phenomena are called physical signs, but for convenience, the word physical is often omitted, and is considered as understood when the term sign is alone used. In this sense of the term signs, or, as restricted to the phenomena obtained by the physical methods just named, it is used in contradistinction to symptoms, the latter embracing all the other phenomena which are manifested in connection with disease. The phenomena thus included under the name signs, are, of course, objective, and will be found to be the most reliable of those by means of which the existence, seat, and character of certain diseases are ascertained.

Late researches have shown that by means of the thermometer symptomatic phenomena of much value may be ascertained. The variations in animal temperature in disease, as determined by the thermometer, have been studied, within the past few years, by Wunderlich in Germany,

Ringer in Great Britain, and many others. For determining conveniently the heat of the body, a thermometer specially adapted to this purpose is requisite. A self-registering thermometer is to be preferred. The bulb of the instrument is to be placed deep within the axilla, and the arm of the patient folded across the chest, the perspiration having been first wiped away. The instrument should remain in this situation for from five to ten minutes. It is a good practical rule to allow the thermometer to remain until a minute passes without any further rise of the mercury, the physician pressing the shoulder of the patient in order to secure close contact of the integument on all sides of the instrument. The normal temperature is from 98° to 99° Fahr. in the great majority of persons; exceptionally it may be half a degree, or even a little more, either above or below this range. The normal fluctuations in different climates or seasons, and under different circumstances as regards exercise, diet, etc., are inconsiderable in comparison with the variations incident to certain diseases.

From observations on healthy persons, Dr. Wm. Ogle deduced the following conclusions respecting diurnal fluctuations of temperature in health: The temperature is at its minimum at about 6 o'clock A.M.; the maximum is reached late in the afternoon, and then there is a fall, which lasts until 6 A.M. The range of the ordinary diurnal fluctuations is not greater than about one and a half degrees, Fahrenheit. Exercise causes a considerable rise. Food causes a rise, which is most marked after breakfast, less so after lunch; and after dinner there is a retardation of the fall which would otherwise occur. Alcohol diminishes the temperature. Tea causes an elevation.[1]

The introduction of the thermometer into clinical investigations is of recent date. That by this means highly important symptomatic phenomena are obtained, facts have sufficiently established. As a means of determining with accuracy the animal temperature, the thermometer is indispensable. The sensation communicated to the hand placed on the skin, on which physicians have heretofore relied for ascertaining the heat of the body, is not to be depended upon; the thermometer in the axilla may indicate an increase of heat, when, to the touch, the surface of the body does not seem to be warmer than in health. Still less reliable are the sensations of the patient; he may complain of coldness when the thermometer indicates increase of heat, and *vice versâ*. By the use of the thermometer, symptoms pertaining to animal heat are rendered objective, and determined with precision. Clinical observation has shown that the axilla is a much better situation in which to place the bulb of the instrument than under the tongue, and a properly constructed instrument may be very conveniently applied in that situation.

The study of the thermometric phenomena in different diseases has developed certain laws, the more important of which may be here stated.

In fevers and other acute diseases, the temperature of the body, as indicated by the thermometer, is always more or less raised, thus substantiating the propriety of the term fever, which signifies increase of heat. If the thermometer in the axilla do not indicate preternatural heat, it is certain that a patient is not affected with a febrile disease. Hence the physician, by means of the thermometer, may be enabled to avoid an error into which he might be led by other symptoms pointing to the existence of a fever or some acute disease. On the other hand, increased heat some-

[1] St. George's Hospital Reports, Vol. I. 1866. Also, Amer. Journ. of Med. Science, July, 1867.

times precedes the development of a febrile disease, which may thus be predicted by means of the thermometer.

The range of the increase of heat in different febrile diseases extends to 110° Fahr., and, as a rule, the amount of increase is a criterion of the intensity of the disease. An increase to 100° or 101°, is evidence of mildness of the disease. If the thermometer indicate steadily 105° Fahr., it is certain that the disease is severe. A persisting temperature above 105° denotes great danger, and if the thermometer indicate an increase to 108°, 109°, or 110° Fahr., death is almost inevitable. The greatest increase of heat has been observed in fatal cases of scarlet fever and tetanus.

The persistence of preternatural heat in any disease denotes its continuance. Whatever may be the other symptoms, the career of the disease is not ended as long as the thermometer indicates increase of temperature. A progressive increase of heat from day to day denotes a corresponding increase of the severity of the disease, and the reduction of heat to the normal standard, as a rule, is evidence of convalescence. The temperature, in some diseases, falls rapidly to the normal standard, and in other diseases the decline is gradual. The term defervescence was introduced by Wunderlich to express the decline of temperature toward the standard of health, meaning, in other words, the approach of convalescence. Some diseases are characterized during the period of defervescence by considerable oscillations of temperature between night and morning, the maximum being at night and the minimum at morning. Typhoid fever is especially characterized by these oscillations toward the end of the febrile career. Hence it is important to employ the thermometer, not only daily, but at least twice a day. The decrease of heat in the morning is favorable, whereas, an increase from night to morning is the reverse. The temperature in some cases of disease remains above the normal standard after the general symptoms denote convalescence; under these circumstances, the patient is in danger of a relapse or the supervention of some other affection. A relapse or the supervention of some other affection is denoted by a rise of temperature after either apparent or real convalescence. During the progress of a fever or any acute disease, a sudden, notable increase of temperature, not sufficient to denote impending death, is evidence of the development of some serious complication or intercurrent affection.

The abnormal variations of temperature which are most apt to occur consist of more or less increase. Diminution below the normal standard is comparatively rare, and has less significance; yet the latter occurs occasionally, and is not without importance. In the course of typhoid fever a sudden and notable decrease of temperature has been observed to precede the occurrence of intestinal hemorrhage. In some cases of disease the temperature is observed to fall notably without improvement in other symptoms, constituting, under these circumstances, an unfavorable symptom. In the collapsed stage of epidemic cholera the heat falls three or four degrees below the normal standard. In conclusion, while the introduction of the thermometer has enabled the practitioner to obtain highly important information concerning diagnosis and prognosis, this information is always to be considered in connection with other facts belonging to the clinical history, and the significance or value of the thermometric phenomena depend, in no small measure, upon the symptoms with which they are associated.

From time immemorial morbid characters of the arterial pulse have been ranked among the most important of objective symptoms. An instrument called the *sphygmograph*, was devised by a French physician,

Marey, with the design to obtain information more extended and accurate than that afforded by the usual digital examination. The sphygmograph is an instrument ingeniously contrived to represent to the eye the movements of the pulse. Applied over the radial artery, a line traced in an upward direction represents the influx of blood from the systole of the left ventricle; from the summit of this line, a line downward and more or less oblique, represents the efflux of blood from the arterial system into the capillaries. The two lines connected at the summit make a diagram which Marey terms the form of the pulse. The upward line traced during the ventricular systole is called the *line of ascent;* the oblique line traced from above downward during the ventricular diastole is called the *line of descent*, and the junction of the two lines at the top is called the *summit.* The number of these diagrams within a given space, of course, shows the frequency of the pulse. Pulse-writing thus consists of a series of diagrams, each representing an arterial pulsation, that is, the movements occurring from one beat of the heart to another.

Comparative observations, by Marey and others, have shown that the form of the radial pulse has certain traits as regards the line of ascent, the line of descent, and the summit, which are physiological, that is, they belong to health, and that certain variations in the form of the pulse are pathological, denoting morbid conditions relating to the circulation. These pathological variations constitute characters symptomatic of disease. Referring the reader to the work by Marey, and to other publications, for an account of the mechanism of the sphygmograph, the rules for its employment, and illustrations of the varied forms of the pulse in health and disease, the more important of the characters which have been ascertained will be here concisely introduced.[1] The characters relate respectively to the line of ascent, the line of descent, and the summit.

The line of ascent represents, measurably, the force of the systole of the left ventricle. Other things being equal, the length of this line is a criterion of the force with which the blood is propelled into the aorta. The length of this line is, however, much affected by the resistance, caused by the tension of the arteries, or, in other words, the amount of blood which the arteries contain at the time of the ventricular systole. In proportion as the tension is great, that is, the arteries filled, the line will be short, although the ventricular systole be strong; and, on the other hand, the line is long in proportion as the tension is small, that is, the arteries unfilled, provided the heart's action be not weak. Bloodletting increases the length of this line, not by increasing the power of the heart's action, but by diminishing the arterial tension. Notable shortness of this line is observed if the heart's action be much enfeebled, as in an advanced stage of typhoid fever, or in cases of local inflammation in connection with a typhoid condition. The line is notably short, and varied with successive pulsations, in cases of mitral cardiac lesions with much insufficiency. A notable disparity in this regard between the two radial pulses exists in certain cases of aneurism affecting the aorta, the innominata, or the subclavian artery.

The line of ascent is either vertical or more or less oblique. If vertical, it denotes quickness of the contraction of the left ventricle; and in proportion to the obliquity the ventricular contraction is slow. A vertical line of ascent, representing rapidity of the arterial movement, denotes a character of the pulse which, to the touch, may give a fallacious sensa-

[1] Physiologie Medicale de la Circulation du Sang, etc., par le Dr. E. J. Marey, Paris, 1863.

tion of force. The shortness of the line may show want of force when, owing to the quickness of the movement, the pulse appears to be strong.

The line of ascent is not always a straight line, but being for a certain distance either approximatively or completely vertical, it then becomes more or less oblique, or the obliquity is increased. This denotes a difference between the first and latter part of the ventricular systole, as regards quickness—at the beginning it is more or less quick, and towards the end, owing to the resistance of the blood in the arteries, it becomes more or less slow. The change is sometimes sudden, and causes a jog or notch toward the upper extremity of the line; this is observed in some cases of aortic cardiac lesions involving obstruction and regurgitation.

The line of descent represents the arterial movements from the cessation of one ventricular systole to the time when the next systole occurs. In general, no movement of the artery is appreciable by the touch during this period. The sigmoid valves of the aorta being closed, the movements of the artery correspond to the efflux of blood from the arteries into the capillaries. The line of descent connects the two succeeding lines of ascent extending from the upper end of one to the lower end of the other. The length of this line will thus depend on the interval of time between the ventricular contractions, that is, on the frequency or infrequency of the pulse. The line is more or less oblique according to the rapidity or slowness with which the efflux of blood from the arteries into the capillaries takes place. The line is sometimes straight and sometimes curved, the convexity looking upward. Morbid characters relating to obliquity and curvature are produced by an abnormal obstruction in the capillary system, and by an abnormal rigidity of the coats of the large arteries.

The line of descent in health has in its course an oscillation more or less marked corresponding to the dicrotic or rebounding pulsation which is sometimes felt by the touch in cases of disease. The sphygmograph shows dicrotism to be a normal character of the pulse, but the rebounding or oscillation, in health, is not sufficient to be felt by the finger. When appreciable by the touch, it is abnormally increased. Marey's observations show the dicrotic character of the line of descent to be marked in proportion as the ventricular systole is rapid, as denoted by a vertical line of ascent; and, on the other hand, the dicrotic character is slight if the contraction of the ventricle be slow, as denoted by obliquity of the line of ascent. Elasticity of the arterial coats is necessary to the presence of dicrotism in a marked degree; in cases of senile rigidity of the arteries it is either lost or but slightly apparent. Slowness of the efflux of blood from the arteries into the capillaries, inducing slowness of the ventricular contraction, diminishes, whereas relaxation of the capillaries, increasing the freedom of this efflux, increases dicrotism. The dicrotism is more marked when the quantity of blood sent out with the ventricular systole is small, than when the quantity is large. Dicrotism is especially marked in continued fever, a fact which Marey attributes to the relaxation of the capillaries. In some cases of disease two or more oscillations may appear in the line of descent, showing a corresponding number of oscillations in the artery during the ventricular diastole. This occurs under circumstances favoring dicrotism, when the frequency of the pulse is notably diminished.

Certain characters relate to the summit, that is, to the connection between the upper end of the line of ascent and of the line of descent. The line of ascent ends when the ventricular systole is balanced by the resistance caused by the blood in the arteries and the arterial coats. Now, if

the systole end directly this equilibrium takes place, and the efflux of blood into the capillaries at once begin, the line of descent forms with the line of ascent an angle more or less acute; in other words, there is no intermediate space at the summit. If, however, the ventricular systole continue after the equilibrium is established, the summit is a plane of variable length. If the equilibrium be exact, the summit is represented by a line perfectly horizontal, its length representing the time between the cessation of the influx of blood into the arteries and the commencement of the efflux into the capillaries. If the equilibrium be not exact, the line forming the summit will not be perfectly horizontal; it will have an inclination upward if the influx slightly exceed the efflux, and, if *vice versâ*, the line will incline downward. The extension of the ventricular systole beyond the ending of the line of ascent, as denoted by a line nearly or quite horizontal at the summit, occurs especially in connection with senile induration or calcification of the arteries.

The study of the graphic characters of the pulse has already afforded important information concerning the circulation both in health and disease. The further prosecution of this study is desirable. The sphygmograph has undoubtedly enlarged our resources for obtaining data for diagnosis and prognosis. The delicacy of the instrument, however, the nicety required for its employment, and the numerous incidental circumstances which are liable to affect its operation, must restrict very much its availability in the hands of the general practitioner.

By means of another instrument for clinical observation, namely, the ophthalmoscope, invented and described by Helmholz, in 1851, a new and important field has been added to the domain of symptomatology. The ophthalmoscope is an optical instrument which enables the physician to observe the interior of the eye. By means of a simple mirror, with a central perforation, a strong light is directed into the eye of the patient, and the observer, through the perforation, obtains a view of the interior of the organ. This is distinguished as the *direct* method of examination. The objects within the eye are seen in their natural position by this method. Another method consists in interposing between the eye to be examined and the mirror, a bi-convex lens. By this method an aerial image of the parts within the eye is perceived, the image being inverted. The latter is called the *indirect* method of observation. For information respecting different instruments, their relative merits, the principles of optics involved in their construction and use, together with all details relating to practical ophthalmoscopy, the reader is referred to either special treatises, or to works on ophthalmology.

Aside from the study of the diseases of the eye, the opthalmoscope brings under observation morbid appearances which are important as symptoms of cerebro-spinal morbid conditions. Certain of these morbid appearances relate to the vessels of the retina and the optic disk. Congestion, or hyperæmia, of these vessels, on the one hand, and, on the other hand, a deficiency of blood, or anæmia, to a certain extent represent corresponding morbid conditions of the nervous centres. An extravasation of blood into the retina may denote, under certain circumstances, changes of the intra-cranial vessels, involving liability to cerebral hemorrhage. Characteristic intra-ocular appearances have repeatedly led to the discovery of renal disease which had previously been unsuspected. Appearances denoting inflammation of the optic nerve and the retina, sclerosis and atrophy, are significant, in certain cases, of intra-cranial or intra-spinal diseases. On the other hand, the absence of morbid appearances within the eye is sometimes of importance as contributing to exclude

lesions or inflammatory affections of the nervous centres. It is a noteworthy fact that observation by means of the ophthalmoscope may show significant intra-ocular morbid appearances when there is neither defect of vision nor any subjective symptoms referable to the eye. Undoubtedly, at the present time, the importance of ophthalmoscopic phenomena is exaggerated by the enthusiasm of some, as it is underrated by others. The careful study of the morbid appearances which are observed in different diseases, in connection with other symptomatic phenomena and post-mortem examinations, for a longer period, is necessary to determine the full amount of reliable information to be obtained from this source. It is certain, however, that the ophthalmoscope is a highly important acquisition of modern clinical medicine as a means of investigating, especially, diseases of the nervous system with reference to diagnosis and prognosis, sustaining, in relation to these diseases, in some measure, at least, the same relation as the stethoscope to the affections within the chest. In treating of the diseases of the nervous system, in the second part of this work, the symptoms furnished by the ophthalmoscope, according to the observations of those who have devoted attention to this field of clinical study, will be noticed. To distinguish with accuracy the varied morbid appearances which are to be observed by means of this instrument, requires an amount of skill which can only be obtained by giving to its use special attention, and by considerable experience. The student or practitioner who desires to become a skilful ophthalmoscopist should, if practicable, obtain practical instruction from an expert, and he will, of course, consult works which treat *in extenso* of ophthalmoscopy.[1]

The symptoms and signs which occur during the course of a disease, are the events which make up its *Clinical history*. This phrase is applied to a description of the manifest phenomena taking place from the beginning to the end of a disease, together with the order of their succession and the laws which govern them. Or, instead of clinical history, it is proper to say the *natural history* of a disease, when the disease is allowed to pursue its course unaffected by disturbing influences of any kind, and when no attempt is made to arrest, abridge, or modify its course by therapeutical measures.

How is the clinical or natural history of a disease to be obtained? There are three methods which may be employed. One method consists in selecting, as types of the disease, a few well-marked cases, and basing the description of the phenomena belonging to the disease on the events observed in these cases. This method is defective, because some symptoms belonging to the disease might be wanting, and some symptoms not belonging to the disease might be present in these few representative or type cases. Moreover, this method is inadequate to show the relative importance of particular symptoms. Another method is to make out a history from recollection, after having observed a greater or less number of cases. A history thus obtained must be imperfect from the obvious inability to retain in the memory all the events which occurred while the cases were under observation, together with the order and relative frequency of their occurrence. The third method is the only one by means of which an accurate clinical history of a disease is to be obtained. It consists, *first*, in the accumulation of a certain number of cases fully and carefully recorded; and, *second*, in an analysis of the recorded cases with

[1] The work by Dr. Allbut "On the Use of the Ophthalmoscope," etc., is the fullest on this subject in the English language. Dr. A. treats of the subject with commendable caution and candor.

reference to the symptomatic phenomena which occurred, the relative frequency of their occurrence, the order of their succession, the number of deaths and recoveries, the duration of the disease, etc. By this method are ascertained events which are constantly present, and, therefore, having an essential relation to the disease; events which are incidental to the disease, being present more or less frequently, and events the presence of which is purely accidental. There are many diseases which have not, as yet, been sufficiently studied after this method, and here, therefore, is ample scope for further clinical labor. Among the diseases which have been studied after this method may be mentioned typhoid and typhus fever and pneumonitis. The knowledge of the clinical history of these and some other diseases obtained by means of this method within late years exemplifies its advantages.

The clinical history of a disease is divided into several distinct periods or stadia, which are commonly called *stages*. The first stage may be distinguished as the invasion or access of the disease. This period dates from the first morbid manifestations, and extends to the time when the disease may be considered as fully developed or established. The duration of this stage varies in different diseases and in different cases of the same disease. Generally the duration is governed by certain laws proper to different diseases. Some diseases are characterized by the abruptness of their development, the stage of invasion being very short or altogether wanting. The *career* or *course* of a disease extends from the date of its development, that is, from the end of the stage of invasion, to the time when the disease may be considered as ended. This period is frequently subdivided into two or more stages. The stage of convalescence embraces the period between the end of the disease and the complete restoration of health.

The clinical history of a disease properly embraces phenomena which may precede the stage of invasion or access. They are distinguished as *precursory* or *prodromic* events; and in some diseases is to be included a period which is to be called the period of *incubation*. The latter term, signifying hatching, relates to the time which elapses after the reception of certain special causes of disease, before any morbid manifestations take place. For example, after inoculation with the virus of smallpox, a certain number of days elapses before any morbid phenomena make their appearance. But, in the mean time, occult operations are doubtless going on in the system, and, when these operations are sufficiently advanced, the period of invasion or access occurs. The significance of the term incubation is thus apparent. Again, the clinical history of a disease should take in phenomena which may occur after recovery from a disease, provided they are dependent upon it. Certain diseases are liable to be followed by certain consequences, which are called *sequelæ* or *sequels*. Thus, after recovery from scarlatina, albuminuria and general dropsy occur in a certain number of cases. These are results of this disease, and hence belong to its history as sequels. In like manner tuberculosis is apt to be a sequel of measles, motor paralysis follows diphtheria, etc.

As a general statement, diseases, in respect of the phenomena and laws belonging to the natural history of them, present in different times and places great uniformity; they are essentially the same in different parts of the world, and they undergo little or no material changes from age to age. This statement is believed to be correct, although it is in opposition to views of late somewhat prevalent. The different phases and modifications which the same diseases may present, not only at different times and places, but in different cases at the same time and place, are, for the most

part, to be explained by the co-existence of affections which may have been antecedent or which are developed as complications.

Diagnosis.

One of the most important of the aspects under which individual diseases are to be considered, is their *diagnosis*. The term diagnosis means the discrimination of diseases, that is determining respectively their character and seat. The practical importance of a correct discrimination of diseases, with reference to their management, is sufficiently obvious. How is it possible to bring to bear upon a case of disease established principles of treatment until the character and seat of the disease are ascertained? Diagnosis and treatment are, in fact, the two practical ends of the study of medicine. Diagnosis is also important with reference to the acquisition of knowledge of the clinical history of diseases. In collecting cases for analysis, if different diseases be confounded, the results of the analysis will be vitiated. In like manner, correctness of diagnosis is the basis of therapeutical experience. Conclusions drawn from the effects of measures of treatment in a series of cases will, of course, prove fallacious if the series include cases of different diseases which have been confounded. Here is a source of not a little of what has been called false experience in practical medicine. Diseases which were formerly confounded are now known to be distinct and readily discriminated from each other. For example, the eruptive fevers, measles, scarlet fever, and smallpox were once considered as different varieties of one disease. Physicians did not undertake, until within a few years, to discriminate between pleuritis, pneumonitis, and bronchitis; now it is not only known that these diseases occur separately, but the diagnostic characters of each are well ascertained, and are sufficient for its recognition. Still more recently, typhus and typhoid fever have been confounded, and, indeed, are still by some considered as one disease.

Differences in skill and tact, among practitioners of medicine, relate especially to diagnosis. In medical consultations it is here chiefly that points for discussion and disagreement are apt to arise. It is here that the want of aid and counsel is oftenest felt by the physician. The diagnosis involves more embarrassment than the management of diseases. This fact is not appreciated by the people at large, many of whom, without any medical education, undertake to decide respecting the nature and seat of the disease whenever their friends are ill.

The diagnosis of a disease may be based on the presence of pathognomonic events. Thus, the characteristic expectoration, or the crepitant rale, denotes the existence of pneumonitis. But, as already stated, there are but few symptomatic phenomena which are truly pathognomonic. Moreover, the few pathognomonic events are not present in all cases of the diseases which they denote if they be present; hence their absence is by no means proof against the existence of the diseases. The characteristic expectoration and the crepitant rale, for example, are wanting in not a very small proportion of cases of pneumonitis. It is evident, therefore, that the diagnosis of a disease cannot often be based on pathognomonic events. And, next in importance, as regards the basis of diagnosis, is the presence of diagnostic symptoms. As a rule, in proportion to the degree of diagnostic significance belonging to the symptoms present and their number, is the diagnosis of a disease easy and positive. In these respects different diseases and different cases of the same disease differ widely; in some instances the diagnostic symptoms present are few in number and

weak, while in other instances they are numerous and strong. It is with special reference to the relative diagnostic value of the different events which make up the clinical history of a disease, that this history is important to the physician if it have been obtained by the true method of study, viz., the analysis of recorded cases.

The laws of disease are often of importance in relation to diagnosis. For example, typhoid fever very rarely affects persons over fifty years of age. When, therefore, persons beyond this period of life are said to have typhoid fever, the chances are that an error has been made in diagnosis. Certain diseases, as a rule, occur but once in the same person. The probabilities, therefore, in a case of doubtful diagnosis, are against the existence of a disease which might otherwise be suspected to exist, if this disease be one of this class, and it be ascertained that the patient has already had the disease. Certain physical signs situated within a circumscribed space at the summit of the chest, denote tuberculous disease, while the same signs, situated elsewhere, might point to some other affection, owing to the law that the tuberculous product, in the vast majority of cases, first occurs at or near the apex of the lung. Similar illustrations might be multiplied indefinitely; the laws regulating the development of a disease, the succession of events, its duration, its sequels, etc., often furnish valuable aid in its diagnosis. Here, too, the practical importance of knowledge of the clinical history of diseases is apparent.

A highly effective method of reaching the diagnosis of a disease is called "reasoning by way of exclusion." In a case of doubt as regards diagnosis, the problem is generally to decide between a certain number of diseases. The existing disease is one of two, three, or more diseases which may be suspected to exist. Now, if it be difficult to decide which one of these is the existing disease, from the positive proof relating to diagnostic events and laws, it may be practicable to decide that there is insufficient evidence of the existence of one or more, and therefore the latter are excluded. By this process of elimination, the number of diseases is diminished, and may be reduced even to one disease; the diagnosis then being made on the principle of exclusion. To illustrate the application of this method, the presence of lancinating pains in one side of the chest, as a prominent symptom of disease, is consistent with the existence of either pleuritis, pneumonitis, or pleurodynia. The question is, which one of these three diseases is the existing disease. In seeking to decide this question, we look for positive evidence of the existence of either one, that is, for pathognomonic or diagnostic symptoms. The characteristic expectoration of pneumonitis would be decisive, if present, but its absence is not proof that this disease does not exist. We cannot exclude this disease by the absence of that symptom. But pneumonitis is frequently accompanied by a crepitant rale, and always leads to solidification of lung, which is revealed by certain auscultatory signs. Suppose these signs to be wanting, we may exclude pneumonitis. The question now is between pleuritis and pleurodynia. Pleuritis is sometimes accompanied by a friction murmur on auscultation, and always, if primary, leads to more or less liquid effusion, the presence of which is demonstratively determined by physical signs. Suppose these signs to be wanting, we may exclude pleuritis. We thus arrive, by way of exclusion, at the diagnosis of pleurodynia, assuming the problem to comprise only these three diseases.

In discriminating a disease from one of several diseases with which it has more or less symptomatic phenomena in common, the amount of positive evidence in behalf of its existence is to be considered, and, also, the evidence against the existence of the diseases from which it is to be dis-

criminated. This comparison of one disease with other diseases, with reference to the positive and negative evidence of its existence, constitutes what is called *differential diagnosis;* and to discriminate a disease in the manner just described is to differentiate it. Thus, typhus and typhoid fever have many symptoms in common, but differ from each other in essential points. The differential diagnosis of these diseases has reference to the circumstances which denote the presence of one, and the absence of the other.

Diagnostic skill is required, not alone in differentiating diseases, but in the discrimination of cases in which diseases are either simulated or their existence fancied. The knowledge and tact of the physician are here not unfrequently called into requisition. The judgment must rest mainly on deviations from the established laws of different diseases as regards symptomatic phenomena, etc., and the absence of objective phenomena which in certain diseases are invariably present. It follows, that the practitioner, other things being equal, will be successful as a diagnostician in such cases in proportion to the accuracy and extent of his knowledge of the phenomena and laws of different diseases. Diseases are simulated for the attainment of certain ends. Thus, soldiers frequently feign diseases with a view to escape active duty, or to obtain a discharge from the service; prisoners feign diseases to secure pardon, or the comforts of a hospital; and cases are not rare of persons simulating various affections to excite sympathy and become objects of interest. Feigning diseases for these or other ends is called malingering, and persons attempting the deception are malingerers. One mode of malingering is to pretend that diseases which actually exist are more severe than they really are. Among the diseases which malingerers are apt to feign are, epilepsy, paralysis, phthisis, aphonia, amaurosis, and insanity.[1]

Practical skill in diagnosis requires mental qualifications which all do not possess in equal measure. Aside from these, the amount of skill which may be acquired will be proportionate to the knowledge of, and familiar acquaintance with, different diseases as regards their clinical histories. It would be absurd to suppose that diseases are to be recognized by an intuitive preception, and that some persons have a peculiar innate gift in this direction. A diagnosis not based on adequate pathological information is always open to more or less of the chances of error which pertain to guessing. The mental qualifications of the skilful diagnostician do not differ essentially from those required for other than medical investigations, namely, accuracy of observation, the ability to reason correctly sound judgment and good sense.

Prognosis.

The division of medicine called *prognosis* treats of the means by which the course and termination of diseases may be foreseen. It is often important to form a correct judgment concerning the way in which diseases are to end, with reference to communications with patients and their friends. They may desire, and, if so, it is proper they should receive, information on this point. Nor should the physician be unmindful of the fact that people in general are apt to estimate his knowledge and ability by the correctness of his judgment in this regard. Recollecting this fact,

[1] For an excellent account of malingering, as regards its various forms, the causes, etc., *vide* article by Dr. Roberts Bartholow in the medical volume of the Reports of the United States Sanitary Commission, 1868, edited by Austin Flint, M.D.

the protection of his own interests, in addition to other considerations, will dictate a certain amount of reserve in his predictions. But a correct judgment as regards prognosis may be important with reference to treatment. Therapeutical measures are sometimes to be withheld in view of the complete hopelessness of the condition of the patient; and, under these circumstances, persistence in the use of remedies is not only superfluous, but likely to do harm. On the other hand, therapeutical measures may be employed with reference to the danger of death, without regard to the nature or seat of the disease. A disease equal in all respects in different cases, may destroy the lives of some, while others recover, owing to the diversity which exists in different persons as regards the ability to sustain and overcome disease; and in the management of diseases, it is often the chief aim of the physician, in the language of Cullen, to obviate the tendency to death.

Prognostics are those circumstances on which a prognosis is based. They relate, of course, mainly to the symptoms of disease. Formerly, before the nature, seat, anatomical changes, etc., of different forms of disease were as well understood as now, all the circumstances connected with diseases were considered with direct and special reference to their significance as prognostics. The consideration of these is appropriate in treating of the principles of medicine, or general pathology; but it will suffice to consider them incidentally in connection with individual diseases. A few points which relate to the physiognomy or obvious appearances, and which render the prognosis unfavorable, may be here enumerated, by way of illustration.

Notable emaciation and pallor, existing in connection with any chronic affection, are unfavorable prognostics. Lividity of the prolabia and face, if persisting, generally denotes great danger. Great frequency and feebleness of the pulse, exclusive of diseases of the heart, and especially in acute diseases, point to a fatal termination. Great prostration is usually an alarming symptom. Spasmodic inspiration, if not dependent on pulmonary disease, precedes the development of coma, except it be referable to hysteria. Coma, if it last more than one or two days, will be likely to end in death. Paralysis of the sphincters, leading to involuntary evacuations, and loss of the muscular power of deglutition, are apt to denote impending dissolution. Impaired capability of feeling the presence of liquid in the air-passages, and inability to make the efforts requisite for its removal by expectoration, are forerunners of the moribund state. Late researches have shown that notable increase of the animal heat, as determined by the thermometer placed within the axilla, if persisting, is to be reckoned among the prognostics denoting imminent danger. Finally, the characters pertaining to the physiognomy which constitute the *Hypocratic countenance*, so called because they were described by the ancient father of medicine, denote the moribund state. These characters are, marked pallor with more or less lividity, pinching of the nostrils, sinking of the eyes, hollowness of the temples, coldness and transparency of the ears, dropping of the lower jaw, etc. The change in physiognomy in this state is so great, that persons are sometimes hardly recognizable. The features, to use a French expression, are decomposed, and a glance at the face often suffices to show that death is nigh at hand.

CHAPTER X.

PROPHYLAXIS—GENERAL THERAPEUTICS.

Experience the Basis of Therapeutical Knowledge—Two Sources of Experience; Analysis of recorded Cases with reference to the Duration or Termination of Diseases, and Observation of the Immediate Effects of Therapeutical Measures—Rational Inference as a Means of arriving at Principles of Therapeutics—Importance of Knowing the Intrinsic Tendencies of Diseases toward Recovery, or otherwise—Active Measures to be employed only when clearly indicated—The Expectant Plan of Treatment—Conservative Medicine—Importance of Hygienic Measures of Treatment—Modes of Dying resolvable into Apnœa and Asthenia—Classification of Therapeutical Measures, according to the Objects to be accomplished, into Prophylactic, Abortive, Curative, Palliative, Hygienic and Sustaining Measures—Consideration of the Elementary Forms of Disease deferred.

THE prevention of disease is an object connected with pathological studies. It constitutes a division of medicine called prophylaxis. It is one of the several aspects under which individual diseases are to be considered. As regards the beneficent fruits of knowledge, it holds a place scarcely inferior to that of therapeutics. Many diseases are preventable by removing or obviating their causes; and it is with reference especially to this application, that the study of causes, or etiology, is of great practical importance. The knowledge already acquired of the causation of certain diseases, has proved of much value. A striking illustration of this is afforded by our present acquaintance with the poisonous effects of lead. It is only within late years that certain diseases have been traced to the action of this poison. The diseases thus produced were doubtless of frequent occurrence before their causation was understood. The physician is now able sometimes to determine that diseases are thus produced, although he may not be able to ascertain in what manner lead has been introduced into the system; characters pertaining to the diseases show that they have originated from this source. This statement is true of that form of paralysis called wrist-drop, and of the form of neuralgia known as saturnine colic.

The recognition of the "germ-theory" as affording the most rational explanation of certain of the special or specific causes of disease, has led to the employment, with great effect, for the prevention of epidemic and infectious diseases, of measures, the efficacy of which apparently depends on their agency in destroying the low forms of animal or vegetable life. In this agency consists the efficiency of certain of the so-called disinfectants. But without positive knowledge of the nature and origin of the causes of disease, we can, to a certain extent, secure exemption from their morbific effects by the knowledge which we possess of certain of the laws regulating their operation. Thus, the special cause of periodical fever, commonly known as malaria, may often be avoided by taking care to avoid exposure to the night-air and by sleeping in an upper story. These causes may be indirectly controlled, to a certain extent, by removing accessory or co-operating causes. It is in this way, probably, that sanitary measures are efficient in protecting against epidemic and endemic diseases. Much has been accomplished in behalf of prophylaxis by these measures, but much more remains to be accomplished. Sanitary reforms

relating to ventilation, sewerage, cleanliness, etc., there is reason to believe, do very much toward the prevention of disease, and, hence, these are among the most important of the modes by which philanthropic efforts may be rendered useful to mankind.

The prospect of diminishing the mortality from certain diseases relates more to prevention than cure. This is true of that disease which contributes so largely to the death-rate in all countries, viz., phthisis. It is unquestionably true that phthisis is much more successfully managed now than heretofore, but it is probable that, under any system of treatment, the disease will prove fatal in a large proportion of cases, sooner or later. A great deal, however, is to be hoped for from the knowledge and avoidance of accessory causes which lead to the development of the disease by acting in conjunction with a congenital predisposition.

Therapeutics.

The division of medicine, devoted to the treatment of disease, is called *therapeutics*. The consideration of therapeutical measures, as regards the evidence of their usefulness, the rationale of their operation, the indications for their employment, etc., constitutes *general therapeutics*. The general principles of therapeutics are usually considered in connection with the principles of medicine, or general pathology. The consideration of the treatment of individual diseases enters into special pathology, or the practice of medicine, and constitutes *special therapeutics*. It will suffice here to offer a few remarks relating to general therapeutics, reserving the different therapeutical measures for consideration, in connection with the treatment of individual diseases, in the second part of this work.

It is needless to offer any remarks on the importance of therapeutics. The treatment of disease is the great end of all our studies relating to pathology, general and special. It is, however, the most difficult of all the branches of medicine for the teacher. It is so, not alone from uncertainty as regards the correctness of therapeutical principles, but because principles, undoubtedly correct in their general application, are to be greatly modified in adapting them to the varied circumstances pertaining to individual cases of disease. The same disease, under different circumstances, may claim, not only widely different modifications of treatment, but therapeutical measures directly opposite in character. There will be abundant occasions for citing illustrations of this fact in treating of individual diseases. It is impossible to formularize rules for the application of therapeutical measures. If this were possible, the practice of medicine would be a mechanical, not a rational, art. All that the teacher and author can hope to do is to present general principles, together with the more important considerations involved in their application. And their successful operation requires, not only knowledge, but reasoning powers, judgment, good sense, and practical tact.

How are the facts and principles of therapeutics obtained? Mainly by experience. The question then arises, how are the results of experience, as regards the utility of therapeutical measures, obtained? There are two sources of experimental evidence in behalf of the utility of a particular method of treatment in any disease. One source of evidence relates to the termination and duration of the disease in a series of cases in which the method of treatment has been employed. The superiority of a method is shown by a larger number of recoveries and an average duration shorter in such a series than in other series of cases treated otherwise. This statistical investigation is open to certain fallacies. No two series of

cases of a disease are in all particulars exactly alike. Cases differ in the degree of severity and extent of disease, in the constitutional condition of patients, in the existence, or otherwise, of complications, and in a great variety of circumstances pertaining to season, climate, age, habits, etc. The results of a comparison of different series of cases, in respect of termination and duration, are to be accepted as the basis of experience only on the ground that the differences in the different series mutually compensate for each other. Hence, the number of cases embraced in a series should be large, and the results of the comparison should be confirmed or corrected by being repeated with successive series of cases collected at different times and places and by different observers. Moreover, pains should be taken to group together cases resembling each other as closely as possible. Observing carefully all proper precautions, the results obtained by this kind of investigation are of great value, if deduced from data faithfully recorded by honest observers and competent diagnosticians. The memory is wholly inadequate for such an investigation. Moreover, recorded facts afford the only security against prejudice and bias. Unrecorded experience is by no means valueless, but it is of little relative value as compared with the results of the analysis of recorded data.

Another source of experimental evidence relates to the immediate effects of therapeutical measures irrespective of the termination or duration of diseases. The usefulness of remedial measures may be apparent from their immediate effects, although there be no proof that the disease has been abridged, and in cases which end fatally. A method of treatment may be useful in a certain number of the cases in a series, although in the majority of cases it may be injurious. For example, let it be assumed that in the larger number of series of cases of pneumonitis bloodletting does harm, it may nevertheless do good in a small number of cases; and, conversely, if it be assumed that this remedy is useful in the majority of cases, it may be pernicious in some cases. So with regard to other measures in other diseases.

It is thus evident that after the utility of particular therapeutical measures in certain diseases, as the rule, has been ascertained by means of a sufficient number of facts derived from the first source of experimental evidence, it is vastly important for the physician to exercise discrimination in the application of these measures to individual cases. And it is to be borne in mind, that, in the practice of medicine, the physician deals with cases of disease separately, not in aggregates. The general principles of therapeutics have a relation to individual cases of disease, not unlike that of the rates of life insurance to the liability to death of particular persons. It is easy to calculate the probabilities of the duration of life in a large number of persons of a given age, and to determine exactly what it is worth to insure the lives of a large number, but no one thinks of applying to an insurance office to know how long he is to live!

Rational inference is a means of arriving at therapeutical principles. If, for example, it be known that a person has swallowed a corrosive poison, reason and common sense at once dictate the propriety of endeavoring either to expel it, or to neutralize it by an appropriate antidote. But, in such a case, experience must be resorted to to know whether either of these objects be practicable, which of the two is to be preferred, and the best means of effecting them. Analogical and *à priori* reasoning may lead to the employment of measures in the treatment of diseases, but the results of experience are necessary to establish their therapeutical value. Talent and genius may be shown in originating methods of cure, but the practical test of their efficacy is afforded by experience. It is true

that false experience has abounded in medicine, but, if experience be open to fallacies, this is true to a far greater extent of theoretical or speculative reasoning. It is worthy of note that our knowledge of the most important remedies is based wholly on experience, without our being able to offer any explanation of their *modus operandi*. Examples are, the salts of quinia as a remedy for periodical fever, mercury and iodine in certain forms of syphilis, etc.

The intrinsic tendency of a disease to recovery, or otherwise, is to be considered with reference to the value of therapeutical measures. Knowledge of the natural history of diseases is important as the true point of departure for therapeutics. Much has been acquired, within late years, in this branch of knowledge, but much yet remains to be acquired. Diseases which were formerly supposed to tend to a fatal result, if not treated by means of active remedies, are now known to end generally in recovery, if let alone. Examples are, acute pleuritis and simple pneumonitis. The importance of increasing our knowledge of the natural history of diseases, by collecting cases which have pursued their course without active treatment, is to be kept in mind by those desirous of contributing to the advancement of therapeutics, and opportunities of accumulating such cases should not be neglected, always provided that the welfare of the patient be not compromised by withholding measures which we have good grounds for believing will prove useful.

It may be laid down as a golden rule in therapeutics that active measures of treatment are only to be employed in cases in which they seem to the physician to be clearly indicated. The severity of disease, and the danger of the patient, be they never so great, do not alone constitute grounds for the employment of active measures. If they be not useful, they will be likely to do harm. Therapeutical measures, in proportion to their power, are powerful for either good or harm, and must, therefore, be either indicated or contra-indicated. In the language of another, the physician "should be content with doing nothing when ignorant how to do good."

The term *expectant*, as applied to the treatment of disease, is often used, and its true sense is not always appreciated. The treatment of a disease by expectation consists in watching carefully its progress, and meeting with appropriate measures unfavorable events as they arise. This plan is not inconsistent with the employment of active measures of treatment; but these are resorted to, not simply because the disease exists, but with reference to events connected with the disease. In this sense of the term, the treatment of a disease is expectant whenever the physician does not attempt to abridge or arrest it, but strives to aid in conducting it to a favorable termination.

The progress of medicine within late years, as regards therapeutics, is characterized by the development of a principle which may be distinguished as *conservatism*. This term may be applied to medical as to surgical practice, and denotes an object which has not heretofore been sufficiently considered, viz., the avoidance of useless and injurious therapeutical measures. Conservative medicine does not interdict the use of the most potential of remedial agencies; but it enforces discrimination and circumspection in their use, recognizing fully their potency for evil as well as for good. The conservative physician is by no means a mere spectator of the progress of disease, but, in wielding the resources of therapeutics, he is careful to preserve the powers of life, following the injunction of Chomel not so much to treat disease, as patients affected with disease.[1]

[1] *Vide* "Conservative Medicine as applied to Therapeutics," American Journal of the Medical Sciences, January, 1863.

The management of cases of disease involves not only the exercise of judgment in the employment, or otherwise, of therapeutic measures, but attention to hygienic regulations. And in a better appreciation of these, the practice of medicine at the present time offers a striking contrast with the past. It may perhaps safely be said that the greater success attending the management of diseases now, than heretofore, is due as much to improvements as regards diet, ventilation, etc., as to the more judicious use of remedial agencies.

In the treatment of diseases involving danger to life, the mode of dying is to be considered. It is often a useful inquiry at the bed-side, by what mode of dying will the case under treatment end fatally if the patient do not recover? The answer to this question will often furnish the indications for treatment, by means of which the danger may be forestalled; and here, it is plain, is the source of indications under circumstances in which it is the aim of the physician to "obviate the tendency to death." It suffices for all practical purposes to reduce the different modes of dying to two, viz., by *apnœa* and by *asthenia*.

Death by apnœa is produced by interruption of the function of respiration. The type of this mode of dying is furnished in cases of strangulation. Death by this mode occurs when produced by affections involving obstruction to the passage of air to the air-cells of the lungs, such as acute laryngitis, croup, œdema of the glottis, foreign bodies in the air-passage, and capillary bronchitis. It occurs sometimes when a considerable portion of the pulmonary organs is rendered incompetent to receive air, as in pleuritis with effusion, pneumonitis affecting both lungs, and acute phthisis. It also occurs when the respiratory movements are arrested by an affection of the medulla oblongata, involving the suspension of the reflux influence by which these movements are sustained. When death occurs from coma, the mode of dying is by apnœa. In this mode of dying, the embarrassment of respiration is out of proportion to the disturbance of the circulation, and, when death takes place purely by this mode, the action of the heart continues for some time after the cessation of respiration.

Death by asthenia, on the other hand, is due to the failure of the circulation. The action of the heart may be suddenly arrested by paralysis from over-distension of the ventricles, by the pressure of blood from an aneurism opening into the pericardium, by pericardial effusion, and by the coagulation of blood within the cavities. But in all diseases which prove fatal by adynamia or exhaustion, the mode of dying is by asthenia, and, when death takes place purely by this mode, respiration continues for a greater or less period after the pulse has ceased to be appreciable at the wrist. Apnœa, however, is frequently combined with asthenia in producing death; the diminished muscular power renders the patient unable to prevent the accumulation of liquid in the air-passages, and the respiratory function also may be interfered with by congestion and œdema of the lungs due to exhaustion. So, also, asthenia is frequently combined with apnœa in fatal affections of the organs of respiration. In fact, in a large proportion of cases, the two modes of dying are combined, either the one or the other mode predominating.

With a view to reference in the second part of this work, a classification of measures of treatment, based on the general objects which the physician aims to accomplish in the management of individual diseases, will be convenient. These objects are embraced in the following classes:—

1. *Prophylactic or preventive measures.*—Vaccination is a preventive measure with respect to smallpox. Quinia, given to protect against inter-

mittent fever, is another measure belonging to this class. Measures to eliminate urea from the blood when the deficiency of this excrementitious principle in the urine is ascertained, before the manifestations of uræmia take place, is another example. The ejection of poisons from the stomach, and the employment of antidotal remedies, belong in the same category.

2. *Abortive measures.*—The measures in this class are those which are employed with a view to arrest the progress of a disease at the outset; to cut it short, or strangle it. Quinia given in large doses in intermittent fever is an abortive remedy. It is not easy to cite many examples of this class. The range in which abortive measures are effective, with our present knowledge, is small. Here is a wide field for further developments in therapeutics.

3. *Curative remedial measures.*—Those measures which abridge the duration of a disease, diminish its severity or danger, and, in general terms, modify or influence it in a favorable manner, may be distinguished as curative. This class is limited to remedial measures, that is, it does not embrace hygienic measures. Quinia is a curative remedy in the cases of periodical fever in which it is not abortive, and, also, in certain cases of neuralgia. Mercury and iodine are curative in cases of syphilis. Opium is a curative remedy in peritonitis, in spasmodic affections like colic, and in sporadic cholera. Numerous other examples of this class might be cited.

4. *Palliative measures.*—The measures belonging to this class are those which are employed with the object of relieving pain or suffering. These measures are directed, not to a disease *per se*, but to the symptoms or effects of a disease. But they may, to a greater or less extent, exert a curative influence. It is conceivable that relief of pain or suffering may conduce to the favorable termination of a disease in some cases.

5. *Sanitary or hygienic measures.*—The measures of this class relate to pure air, temperature, diet, cleanliness, moral influences, etc. Medicine has certainly derived as much advantage from this class, of late years, as from curative remedial measures. The improvements which have taken place in the management of diseases, as regards air, water, food, exercise, etc., are very great, but there is room for still further improvement.

6. *Sustaining or supporting measures.*—The measures of this class consist of tonic remedies, stimulants, especially alcoholic, and nutritious alimentation. The objects are to obviate a tendency to death by asthenia, and to forestall a degree of prostration dangerous to life. Sustaining measures are applicable to the treatment of all diseases which, if they prove fatal, will destroy life by asthenia, and they are indicated with an urgency corresponding to the danger of death by this mode. These, together with palliative and hygienic measures, constitute the treatment of all diseases which cannot be arrested, and which are not amenable to curative measures. Not a few diseases will be found in this category.

The terms *analeptic* and *restorative* are applied to measures relating to diet, regimen, and remedies, when the object is, in general terms, to bring the system back to its normal condition. Supporting measures have reference more especially to acute diseases which threaten life. Analeptic measures are those called for when the general health is deteriorated, although there may be no disease which involves danger to life; when in other words, the system is *below par*. They are often called *building up* measures, and are indicated in a large majority of disorders and chronic ailments.

A very good division of therapeutical indications is adopted by Niemeyer, namely, 1st, the indications which relate to the removal or abate-

ment of causes—these may be distinguished as Causal indications; 2d, Symptomatic indications, or those having reference to the symptoms, irrespective of the nature and seat of the disease; and 3d, Pathological indications, that is, the indications derived from a knowledge of existing diseases considered with reference to their character, situation, and intrinsic tendencies.

Measures of treatment are sometimes classified and named from their action being in opposition to a particular morbid condition; thus, formerly, the term *antiphlogistics* was much in vogue, this name being applied to measures which were considered as opposed to inflammation. Of late, certain measures, the immediate effect of which is the diminution of the temperature of the body, are often distinguished by the name *antipyretic*. Quinia and some other remedies are called *antiperiodic*, from their efficacy in arresting affections which are characterized by intermittency; remedies which are antagonistic to the effects of syphilis are called *antisyphilitic*, etc. It is, however, an error to suppose that it is a governing principle in therapeutics to employ remedies or measures, the action of which upon the body in health is the opposite of the effects or manifestations of disease. This principle is expressed by the term *allopathy*, a term applied by Hahnemann to denote a therapeutical doctrine the reverse of *homœopathy*. Legitimate medicine recognizes no such restricted and exclusive dogma as these two terms alike denote; and, hence, the name allopathy is to be by no means accepted, but considered as a term of unmerited reproach.

An important precept in therapeutics is the observance of simplicity in prescribing remedies. As a rule, curative remedies differing in their effects, should not be given in combination or at the same time. Different remedies should be conjoined only when they co-operate for a common object, such, for example, as a cathartic or a diuretic operation. This precept is important, not only because different remedies are likely to conflict with each other, but because it is difficult to judge of their efficacy severally. To observe the separate effects of particular remedies in individual cases is essential in order to obtain that experience which will be useful to the same patient at other times, and in other cases of the same disease. The experience of the physician accustomed to prescribe together multifarious remedies, must, of necessity, be confused and uncertain. Moreover, complicated prescriptions are objectionable on the score of their tending to invest the practice of medicine with an unworthy mystery. These remarks, of course, do not apply to uniting with a curative remedy medicines designed to correct incidental effects which it is desirable to avoid, and to diminish the repulsiveness of a remedy, or to secure for it a better tolerance. These objects, in the combination of medicines, are important. Not the least conspicuous of the modern improvements in medical practice relates to the use of alkaloids and concentrated remedies, together with other contrivances to divest remedies of a nauseousness which was formerly, as a matter of course, associated with the idea of a medicine.

A considerable share of medical practice consists in the treatment, not of the individual diseases which are to be taken up in the second part of this work, but of disturbances of health which have no well-defined places in medical nosology. These disturbances often proceed from the operation of morbid causes, intrinsic or extrinsic, which it should be the aim of the physician to ascertain, and the removal of which, if possible, is to be effected. The development of serious diseases may, doubtless, in this way frequently be prevented. In many cases, the knowledge and skill of

the physician are called into requisition to determine that no serious or well-defined disease exists. It is by no means the sole office of the physician to treat diseases. To indicate the causes of disease, more especially the voluntary violations of the laws of health; to enjoin such a course of life as shall seem most likely to afford security against disease, and promote physical and mental vigor; to decide in cases of disease against the employment of active therapeutical measures,—these are duties not less important than the employment of potent remedies whenever the latter are required.

In the management of cases of disease, mental influences are often of not a little importance. The physician may in many cases effect much by judicious encouragement, and by stimulating the voluntary efforts of the patient. Hopefulness and a strong will are curative agencies which are frequently powerful auxiliaries to medicinal remedies, and they are sometimes more potent than drugs; on the other hand, despondency and a lack of resolution have a depressing effect which, in some cases, tells greatly against recovery. Certain disorders may be produced and prolonged indefinitely by mental causes, the removal of which is essential to a cure. Too much concentration of the attention on the functions of the body is a common source of disorder among persons who, from want of occupation, unfortunately become unduly engrossed with their physical condition; and, in such cases, to divert the mind from the body is an object not less important and difficult than, in other cases, to secure a proper degree of care for exising ailments. The ability to exert those mental influences which are suited to different cases, conduces, in no small measure, to success in practice; and this ability requires, in addition to natural powers, knowledge of human character, and a tact which is acquired by experience. A cheerful mien, and manners calculated to inspire confidence, are by no means beneath the attention of the physician, but, on the contrary, they are to be cultivated as highly useful professional attainments. Medicine, in its practical aspect, involves knowledge, judgment, and skill, as regards, not only the employment of the several classes of the therapeutical measures which have been enumerated, but the mental influences suited to the circumstances peculiar to individual cases of disease.

The history of medicine shows many and great mutations in the prevailing doctrines of therapeutics at different periods. The medical practice of the present day in many respects is in striking contrast to that current a half century ago; and it is by no means improbable that a comparison with the present day at the end of the next half century, will reveal points of contrast not less striking. These mutations, so far from being a reproach, illustrate the progressive character of medicine. Therapeutical principles can never become unchangeably fixed until the utmost limits of attainable pathological knowledge are reached, and nothing further remains to be ascertained by experience. It would be absurd to claim for medicine this perfectibility; but continued improvement in the management of disease may be reasonably expected. Future improvement will doubtless embrace the addition of new remedies and measures of treatment, more extended and precise knowledge of those already in use, and the correction of errors which probably now, as heretofore, render sometimes the efforts of the physician not only inadequate but prejudicial.

The uniformity of the laws of disease at different periods and places has been already referred to. The bearing of this on the stability of therapeutics is obvious. So, also, with reference to the same application, it is important to assume that the system of man is not liable to alterations

which render the operation of therapeutical agencies widely different at periods not far removed from each other. The opinion held by some that such alterations have occurred within the memory of those now living, does not rest on any solid basis. Admitting to the fullest extent diversities attributable to race, climate, occupations, hereditary influences, etc., these do not invalidate the statement that the human constitution remains essentially unchanged, as regards the application of established therapeutical principles. Were the truth otherwise, it would strike at the root of medical experience. If changes requiring a revolution in therapeutics were liable to occur with each successive generation, it is evident there could be no permanent principles of medical practice; the fruits of experience in our day, which so many are striving to develop, would be not only useless, but an injury to those who are to come after us.

This chapter concludes the first part of this work, the part devoted to the Principles of Medicine, or General Pathology. A succinct account of the changes belonging to morbid anatomy, and of the known morbid conditions of the blood, has been presented, together with certain distinctions, definitions, and general considerations relating to etiology, symptomatology, diagnosis, prognosis, prophylaxis, and therapeutics. These subdivisions of the principles of medicine, or general pathology, have been considered as fully as is deemed important by way of preparation for entering on the study of individual diseases. The latter will be considered in the remainder of the work, which is to be devoted to the Practice of Medicine, or Special Pathology.

Certain topics which might properly be included among those considered in the first part of this work, are reserved for consideration exclusively in connection with individual diseases. The morbid conditions constituting what may be called the *elementary forms of disease*, are thus reserved. Under the head of elementary forms of disease are embraced those morbid conditions, entering into a greater or less number of individual diseases, which, with our present knowledge, constitute the primary deviations from healthy conditions. They are, in other words, the simplest forms into which morbid conditions are resolvable. These elementary forms enter into different individual diseases, as the elementary tissues either constitute or combine to form the different organs of the body. Inflammation is an example of an elementary form of disease giving rise to a host of individual diseases. Fever, considered as an essential form of disease, is another example. The consideration of these and other elementary forms belongs appropriately to the principles of medicine, or general pathology, but it will suffice to consider them in treating of the individual diseases to which they give rise, or into which they enter. Our present knowledge of the elementary forms of disease is extremely limited. This will be apparent, in treating of individual diseases, when the inquiry arises respecting what is known of the primary, essential morbid conditions which they involve.

The consideration of certain measures and plans of treatment belong to general therapeutics. Thus, in the present chapter, bloodletting, the use of mercury, etc., as applied, not to any particular disease, but to groups of diseases, might with propriety have been considered. It will be more convenient, however, to offer such general considerations relating to these topics as may be deemed important, in treating of the application of therapeutical measures to the management of individual diseases.

PART II.

PRACTICE OF MEDICINE, OR SPECIAL PATHOLOGY.

INTRODUCTION.

Of the different aspects under which Individual Diseases are to be considered, in treating of the Practice of Medicine, or Special Pathology—viz., Anatomical Characters, Clinical History, Pathological Character, Causation, Diagnosis, Prognosis, Prevention, and Treatment—Sense of the Term Individual as applied to a Disease, and the several Grounds of Individuality—Varieties of a Disease—Definition of the Terms Acute, Subacute, and Chronic—The Symptoms or Events incidental to Disease sometimes, for convenience, considered as Individual Diseases—Self-limited Duration of Certain Diseases—Nosology—Nosological Arrangement adopted in this Work.

THE *Practice of Medicine, or Special Pathology*, treats of individual diseases. In this department of medical study, individual diseases are considered under several different aspects. One of these aspects relates to the appreciable changes found after death. These changes belong to morbid anatomy. Some diseases are characterized by morbid appearances in the parts affected, and other diseases are not accompanied by any lesions which are appreciable. The latter are distinguished as *functional affections*. Of the morbid appearances occurring in connection with different diseases, some are peculiar to one disease, and others are common to a greater or less number of diseases. The term *anatomical characters* of a disease expresses the changes, belonging to morbid anatomy, which occur in connection with that disease. This term will be adopted as the title of the first aspect under which will be considered generally, in the following pages, those diseases which are not functional.

Another aspect relates to the phenomena or events which compose the *clinical history* of a disease. Under this head will be embraced precursory or prodromic events, the symptoms which accompany the access, and those which occur during the career of the disease under consideration, the order of their succession, the laws regulating the development and progress of the disease, etc. This will constitute the second of the different aspects under which individual diseases, severally, are to be considered.

A third aspect relates to the *pathological character* of a disease. Under this head will be presented what is known of the nature and seat of the morbid conditions which constitute, or enter into, the disease under consideration. In treating of each individual disease, the inquiry will arise under this head, what are the primary, essential deviations from the conditions of health; in other words, what morbid actions or processes constitute the point of departure for the manifestations of the disease? This inquiry will often lead to a confession of the imperfection of existing knowledge.

A fourth aspect relates to *etiology*, or the *causation* of a disease. Under this head the cause or causes of each individual disease will be considered.

Here, too, the imperfections of existing knowledge will be frequently apparent.

A fifth aspect relates to *diagnosis*, or the discrimination of a disease. The application of the methods of investigation which, by means of symptoms, laws, etc., enables the physician to recognize the disease under consideration, and to distinguish it from other diseases, will be considered under this head. Physical signs, whenever these are available in the diagnosis of a disease, will be embraced under this head.

A sixth aspect relates to *prognosis*. Under this head will be considered the intrinsic tendency of a disease as regards its termination in death or recovery. The circumstances which denote, on the one hand, a favorable, and, on the other hand, an unfavorable progress of the disease under consideration, will come under the head of the prognosis. And the consequences more or less remote, or sequels, may sometimes be conveniently embraced under this head.

A seventh aspect relates to the *treatment* and *prevention* of a disease. The consideration of the treatment of each disease will embrace the indications for therapeutic measures, and the remedies which experience has shown to be useful in that disease. Hygienic measures also will enter into the consideration of treatment. Prophylactic measures of treatment will claim consideration in treating of some diseases, and the measures which remove or obviate the causes of disease, will often be found to be not less important than the judicious application of principles of therapeutics.

Before entering upon the consideration of individual diseases, it may be well to inquire what is meant by this use of the term individual, and whence does a disease derive its individuality. An individual disease differs from other diseases sufficiently for it to be regarded as separate and distinct. The sense of the term individual, in this application, is analogous to that of species, in natural history. The individuality of a disease is established by distinctive features pertaining to its clinical history. These distinctive features may be derived exclusively from the seat of the disease. Thus, pleuritis and pericarditis are inflammatory affections of a serous membrane, and have essentially the same pathological character; but the different anatomical relations of the pleura and pericardium furnish sufficient points of distinction to constitute each of these affections an individual disease. In other instances, distinctive features are derived from the actions or processes belonging to disease. Inflammatory affections, for example, differ essentially from those which are not inflammatory. Again, certain diseases derive each an essential dictinction from its dependence exclusively on a special cause. It is sufficient to show that a disease is produced by a special cause to establish its claim to be regarded as an individual disease.

An individual disease is to be distinguished from individual cases of disease. An individual case of disease has a relation to an individual disease, like that of a particular man to the species *homo*. The study of individual cases of disease belongs to clinical medicine. Some individual diseases embrace several varieties. Empyema and pneumo-hydrothorax may be considered as varieties of pleuritis, both consisting in inflammation of the pleura, the former differing from ordinary pleuritis in the fact that the liquid contained in the cavity of the pleura is purulent, and the latter differing in the fact that air and liquid are contained in that cavity. The several types of intermittent fever, distinguished as tertian, quotidian, etc., are different varieties of one disease. In the progress of medicine, certain diseases have come to be considered as essentially distinct, which were formerly regarded as different varieties of one disease. This is true

of all the eruptive fevers. It is probable that certain diseases now considered as individual will be found to be composed of two or more. Bright's disease of the kidneys may be cited as an example. It is still a mooted question whether certain diseases are essentially distinct; for example, typhus and typhoid fever are by some considered as identical, differing sufficiently to be regarded as different varieties of one disease, but not enough to establish the individuality of each.

Differences as regards severity and duration constitute a basis of the division of a disease into varieties. The same disease may be either *acute*, *subacute*, or *chronic*. A disease is acute when it has a certain degree of intensity and runs a rapid career. In general, an acute disease is of sufficient gravity to confine the patient to the bed. The subacute variety of a disease has less intensity, frequently not compelling the patient to keep the bed, and perhaps not preventing him from being about, or even pursuing his usual occupation. The chronic variety exists when a disease is subacute and has continued for a considerable period. Acute, subacute, and chronic rheumatism may be cited as illustrating these three varieties of one disease. Some diseases are never chronic. This term, for instance, is not applicable to typhus or typhoid fever. The division into varieties, based upon the differences just named, is especially applicable to inflammatory affections.

The list of individual diseases embraces some, recognized as such for the sake of convenience, which, in reality, are only effects or symptoms of diseases. Jaundice, for example, is an effect or symptom occurring in connection with different affections. Dropsy is in the same category. It is, however, convenient to consider jaundice and the different forms of dropsy as if they were individual diseases. In fact, if we were better acquainted with the primary or elementary forms of disease, it would probably appear that not a few of the affections now considered as individual, are only manifestations of morbid conditions at present occult—the latter constituting the true diseases.

A point of distinction among diseases, interesting and of much practical importance, relates to duration. Some diseases continue for a definite period, never exceeding certain limits in this regard. The duration of certain diseases is regulated by fixed laws; that is, they never end until after the lapse of a certain number of days, and never exceed a certain number of days in their continuance. The continued and eruptive fevers are examples of diseases, the duration of which has definite limits. Intermittent fever, on the other hand, has no fixed or definite duration, if its course be not interfered with. Diseases which tend intrinsically to end after a certain time, are distinguished as *self-limited*. The laws of different diseases with respect to self-limitation are often to be taken into account in the employment of therapeutical measures, and it is obvious that these laws are to be considered in estimating the amount of curative influence exerted by methods of treatment.

In treating of individual diseases, some classification of them is essential. The classification of diseases constitutes a division of medicine called *nosology*. The history of medicine furnishes numerous nosological systems, the relative merits of which it would be quite useless to discuss. Undoubtedly, the most scientific mode of classifying diseases would be to arrange them after essential points of distinction, relating to their pathological character. But, with our present knowledge of the pathological character of different diseases, to do this is impracticable. A nosological arrangement on this basis must be deferred for a future period, when pathology has advanced far beyond its condition at this time. The same

remark is applicable to any arrangement based on differences as regards the causes of diseases. Our present knowledge of etiology is too limited to serve as the basis of a permanent nosology. Inasmuch as the chief object of a classification is convenience, the proper course to be pursued, evidently, is to adopt a provisional plan which will best subserve this object. And the most convenient classification, at the present time, is that which has of late years been adopted by the majority of writers and teachers. This consists in dividing diseases into, *first*, *general*, and, *second*, *local*. General diseases are those which involve more or less disturbance of the whole system, this disturbance not having been preceded by any known local affection, local affections, if they occur, being developed secondarily. To this class belong the essential fevers. Under the head of constitutional diseases, it is convenient to include some in which the local manifestations have no fixed seat, and sometimes differ in character. Rheumatism and gout are constitutional diseases, the chief manifestations consisting of local affections differently situated in different cases and at different periods in the same case. The local affection, however, is, in each, essentially the same wherever seated. Syphilis is another constitutional disease manifesting itself in local affections which differ, not only in situation, but in character. The want of fixedness or uniformity in the seat of local affections proceeding from constitutional disease, and their diversity in character in some instances, are the grounds for placing certain diseases in this class. A large proportion of the affections, nosologically considered as local, probably proceed from constitutional disease; but as the local affections are fixed and uniform, and our knowledge of the constitutional disease is, for the most part, inferential, it is more convenient to arrange them in the second division.

The second division, or local diseases, will embrace all which are not reckoned as general, or constitutional. The local diseases are far more numerous than those in the first division. It is necessary to arrange them into subdivisions. And the most convenient plan is to distribute them into groups, corresponding to the arrangement of the different organs of the body into physiological systems. According to this plan the different local diseases are subdivided as follows:—

1. Diseases affecting the respiratory system.
2. Diseases affecting the circulatory system.
3. Diseases affecting the digestive system.
4. Diseases affecting the nervous system.
5. Diseases affecting the genito-urinary system.

The foregoing arrangement of local diseases will be adopted, and they will be considered in sections corresponding to the groups just enumerated; afterward a section will be devoted to general diseases.

Of the diseases belonging to these several groups, those only will be considered which are medical, as distinguished from surgical. The latter will include affections which are either external or in accessible situations. Thus, affections of the mouth, throat, and nasal passages, of the anus and rectum, of the urethra and bladder, of the eye and ear, and of the vagina and uterus, fall within the province of surgery. Diseases of the skin, being external, belong to surgery, notwithstanding they receive special attention from the physician perhaps oftener than from the surgeon. As an additional reason for not including them among the diseases to be considered, there are numerous treatises devoted specially to their consideration.

SECTION FIRST.

DISEASES AFFECTING THE RESPIRATORY SYSTEM.

CHAPTER I.

Division of the Diseases affecting the Respiratory System into Inflammatory and Non-inflammatory—Acute Pleuritis—Anatomical Characters—Clinical History—Pathological Character—The Natural History of Inflammation, and our Knowledge of its Essential Nature—Causation of Pleuritis—Diagnosis—Prognosis.

OF the diseases affecting the respiratory system, an obvious division is based on a difference in pathological character, as regards the existence, or otherwise, of inflammation. The inflammatory affections in this group of diseases are seated respectively in the three most important of the structures which are comprised in the organs of the respiratory apparatus, viz., the mucous membrane lining the air-passages, the serous membranes which invest the lungs, and the pulmonary parenchyma. Exclusive of affections seated in the larynx and trachea, inflammation affecting the structures just named gives rise to three important diseases, viz., pleuritis[1] or pleurisy, pneumonitis or pneumonia, and bronchitis. Beginning with these inflammatory affections, they will be treated of in the order in which they have just been enumerated. The first disease to be considered, viz., pleuritis, may exist as an acute and as a subacute or chronic affection. These two varieties of the disease will claim separate consideration. Other varieties, to be considered separately, are empyema and pneumo-hydrothorax. It will be convenient to notice, in connection with these varieties of pleuritis, the dropsical affection known as hydrothorax.

Acute Pleuritis.

The pleura, anatomically, is essentially similar to other serous membranes. It is composed of white non-elastic and yellow elastic fibres. It is divided into two layers, viz., the visceral and parietal. The free surfaces of these two layers are smooth, polished, and moistened with halitus. It is transparent, receiving a certain number of blood-corpuscles, but not sufficiently aggregated to be visible. The nutrient vessels ramify in the sub-serous areolar tissue. It forms in each side a shut sac. Its offices are to afford support and allow movement without injury from friction.

Anatomical Characters of Acute Pleuritis.—The first noticeable appearance, could the inflamed part be seen during life, would doubtless be redness from an increased quantity of blood, chiefly contained in the vessels beneath the membrane. Redness here, as in other situations, may

[1] With a view to uniformity as regards nomenclature, the terms pleuritis and pneumonitis are used instead of pleurisy and pneumonia.

diminish and disappear after death. It is supposed that, for a brief period after the commencement of inflammation, the membrane is abnormally dry, from suppression of the halitus which moistens it in health. Liquor sanguinis, or blood plasma, begins soon to exude, the fibrin which it contains coagulates, and characters sufficient to show the existence of inflammation are now present.

If the disease prove fatal within two or three days, the pleural cavity contains a greater or less quantity of liquid, the amount varying considerably in different cases. The liquid is not everywhere clear, like the serum of the blood, or a purely dropsical effusion. The upper portion is usually clear, if the body have not been much disturbed in opening the chest, but near the bottom it is turbid from the admixture of coagulated fibrin or lymph. The pleural surfaces are more or less coated with lymph which, at this period of the disease, is soft and easily removed. The amount of lymph varies considerably in different cases. Its presence is essential as a criterion of inflammation. The membrane loses a portion of its transparency from serous infiltration beneath it; it is somewhat swollen, and its epithelium is exfoliated. Redness, from sub-serous congestion, may or may not be apparent. Small extravasations of blood or ecchymoses are not unfrequently observed.

On examination after death occurring at a later period, the pleural sac is found to contain a certain quantity of liquid, varying from a few ounces to several pints, with flocculi of lymph at the bottom of the liquid. Lymph may be found to coat the greater part of, or even entirely, the pleural surfaces, or it may be limited to patches. It is usually more abundant on the parietal than on the visceral surface. It is more dense than at an earlier period, and is disposed in the form of a layer or a series of layers. The layers of lymph present a membraniform appearance without organization. A layer of lymph sufficiently dense to be stripped off is properly called a false membrane. The name false membrane, which is often applied to the adventitious tissue subsequently produced, is more correctly limited to an unorganized layer of lymph or fibrin. It may adhere with considerable tenacity to the pleural surface, and if the opposing surfaces be not separated by liquid, they may be pretty firmly agglutinated by means of the intervening lymph. The density of the lymph and the firmness of its adherence are evidences that the exudation is not of recent occurrence.

The presence of serum and lymph, in varying relative proportions, in other words, a sero-fibrinous liquid, thus, is characteristic of simple acute pleuritis. The liquid in the pleural cavity occupies space at the expense of the volume of the lung. As it accumulates, it compresses the lung, the latter occupying a space reduced in proportion to the amount of liquid. If the pleural surfaces be free from old adhesions, and not agglutinated by lymph, the relative situations of the liquid and lung will vary according to the position of the body. If the patient be sitting or standing, the liquid gravitates to the bottom of the sac, and rises to a height proportionate to the quantity. If the patient be recumbent on the back, the liquor gravitates to the posterior part of the chest, and the lung will descend in front, more or less, in a direction toward the diaphragm. In like manner, if the patient lie on the face, the liquid occupies the now depending anterior part of the chest, and the lung will descend behind. These changes in relative situation are frequently available in determining, by physical signs, the existence of liquid in the pleural cavity.

If the disease progress favorably, the liquid diminishes progressively, with variable rapidity in different cases, by endosmosis or absorption. It diminishes often with considerable rapidity until it is reduced to a small

or moderate quantity, and then the absorption takes place slowly—a clinical fact probably due to the increasing density of the liquid from the larger relative proportion of lymph as the serosity lessens, and to the increased density of the layers of lymph with which the pleural surfaces are coated. The absorption of the lymph occupies a considerable period after all the liquid has been absorbed. In the mean time, the pleural surfaces, coming into contact over their entire area, are agglutinated by means of the intervening lymph, and this exudation is replaced by a newly-developed adventitious tissue which unites by permanent adhesions the surfaces in apposition. It is to be noted that the union by means of the adventitious tissue is not mechanical, as when the surfaces are agglutinated by lymph, but vital, that is, by an organized membrane. The adhesions may extend over the whole of the pleural surfaces, and then the serous cavity is obliterated, or they may be limited to certain portions, in the latter case constituting ligamentous bands, which, being observed by some of the older anatomists, were supposed to have been produced by inordinate laughter! This true membranous tissue has been supposed to be organized fibrin or lymph. Many, if not most, pathologists at the present time have abandoned this view of its production. It is, however, a question concerning which pathologists are not agreed, whether the new tissue is generated spontaneously, within the exudation, the latter being then a blastema; or whether its production be due to proliferation, in other words, a vegetation or hyperplasia of the areolar tissue of the pleura. This pathological question has been referred to in the first part of this work.[1]

The adhesions by means of organized tissue take place during convalescence. At first, they are weak and liable to be broken by active exercise, or in acts of coughing. Hemorrhage may in this way occur. They become stronger with time, so that when death occurs after the lapse of several weeks or months, the lung is detached and removed from the chest with considerable difficulty. After a time, all the lymph disappears, and nothing remains but the newly-produced tissue. It may be remarked, in passing, that after the serous cavity is thus abolished, there is no space for the effusion of liquid to constitute hydrothorax, and œdema of the lung may take its place under circumstance which give rise to dropsical effusion in the opposite side. A case has come under my observation exemplifying this fact. It is also to be remarked that these adhesions, however extensive, occasion no appreciable disturbance of respiration. They are, in fact, innocuous, and perhaps confer exemption from recurrence of pleuritis on the same side. Nor do they give rise to any distinct physical signs.

The accumulation of liquid in acute pleuritis may take place in such quantity as to fill the cavity of the pleura, compressing the lung into a small solid mass. The compressed lung loses all the physical characters dependent on the presence of air in the pulmonary vesicles. It resembles a mass of flesh, and is therefore said to be *carnified*. The pulmonary structure, however, remains intact, and it is capable of being inflated, after death, nearly or quite to the same extent as if it had not undergone this compression. A similar expansion may take place during life, after the absorption of the liquid. So large an accumulation of liquid, however, occurs much oftener in chronic than in acute pleuritis.

In cases of acute pleuritis which pursue a favorable course, absorption of the liquid commences a few days after the accumulation has reached the maximum. Should the quantity remain stationary or the diminution take place very slowly, after the lapse of two or three weeks the disease has

[1] *Vide* pp. 34, 35.

become chronic. The greater part of the liquid is sometimes absorbed, and vital adhesions take place between the larger portion of the pleuritic surfaces, leaving a circumscribed space in which a certain quantity of liquid may remain for an indefinite period. The disease then eventuates in a circumscribed chronic pleuritis.

The foregoing description of the anatomical characters of acute pleuritis relates to its occurrence as a primary disease so far as any other pulmonary affection is concerned. Occurring independently of any prior disease of the lung, the inflammation is general, that is, it extends over the greater part or the whole of the serous membrane. It is otherwise when pleuritis occurs consecutively to another pulmonary disease. Occurring, as it does quite constantly, as a complication of pneumonitis and pulmonary tuberculosis, the inflammation is limited to a portion of the membrane; the pleuritis is circumscribed. And circumscribed pleuritis, developed thus as a secondary affection, is rarely accompanied by liquid effusion. It is distinguished from general pleuritis by this fact; the exudation of fibrin only occurs, and the pleuritis is said to be dry. Primary or idiopathic pleuritis is seated in the left oftener than in the right side.

Clinical History.—The most convenient division of acute pleuritis into stages, is to consider as the first stage the period from the attack to the time when an appreciable quantity of liquid effusion has taken place; the second stage will extend to the time when the liquid begins sensibly to diminish, and the third stage will comprise the period occupied in the removal of the liquid. The first stage, or the period anterior to an appreciable amount of liquid effusion, is usually of short duration. The physical signs may show the presence of liquid within a few hours from the date of the attack. The stage rarely extends beyond twenty-four hours. The second stage is of variable duration. The accumulation of liquid may go on with more or less rapidity. When the maximum amount is reached, the quantity may remain stationary for some time, or absorption may speedily begin. The liquid may diminish under the effect of treatment, and renewed effusion take place. The disease does not, of course, advance beyond the second stage in the cases in which it eventuates in chronic pleuritis. If a considerable quantity of liquid remain at the end of from two to three weeks, the disease is to be considered as having become chronic. In cases which pursue a favorable course, considerable progress should be made in the removal of the liquid after this lapse of time. The duration of the third stage, or the stage of absorption, is quite variable. Generally some liquid remains when the general symptoms denote convalescence, and even after the patient has apparently recovered. The physical signs may show the presence of lymph for some time after the date of convalescence. From what has been stated, it follows that the duration of the career of the disease is from two to three weeks.

The invasion is sudden, and often without premonition. In a certain proportion of cases, however, some degree of pain or soreness is felt for one, two, or three days before the development of acute inflammation. This fact, which other observers have noted, has repeatedly occurred among the cases that have fallen under my observation. The development of acute inflammation is characterized by symptoms which sufficiently mark the date of its occurrence. It is sometimes ushered in by a well pronounced chill, accompanied perhaps with rigors. Chill and rigors, however, are by no means so frequent, nor, as a rule, so marked as in cases of pneumonitis. Not unfrequently chilly sensations and slight shivering only are experienced.

Pain in the affected side attends the onset of acute inflammation in a large majority of cases. The pain is usually intense. It is sharp, cutting, or lancinating in character. It is felt especially in the act of inspiration; it increases during inspiration, often becoming so severe that the act is instinctively arrested before being completed. Coughing and sneezing occasion severe pain. The movements of the body are painful, but in a far less degree than the respiratory movements. The pain is referred to the middle and lower third of the affected side of the chest, and is usually diffused over the anterior, the lateral, and sometimes the posterior portion. It is not, as a rule, circumscribed or limited to a small space. The morbid sensitiveness of the inflamed pleura seems to me adequate to account for the production of acute pain, as a result of the movements of the pleural surfaces upon each other, and the stretching of the membrane, without requiring the hypothesis that either intercostal neuralgia, or an affection of the costal muscles, is superadded to the inflammation. Pain, with the characters just described, is almost uniformly present in acute pleuritis, but cases occur in which it is not marked, and even wanting, other symptoms showing the inflammation to be acute.

Febrile movement is coincident with the development of the inflammation. The pulse is increased in frequency and in strength. The temperature of the surface is raised. The thermometer in the axilla shows more or less intensity of fever, but the rise rarely exceeds 102°. As a rule, this criterion of fever denotes less than in cases of pneumonitis. The usual concomitants of symptomatic fever, viz., thirst, anorexia, pain in the head and loins, restlessness, muscular weakness, etc., are more or less marked. The intensity of the febrile movement, and of the general or constitutional disturbance, varies much in different cases of this, as of other inflammations, and is not to be taken as evidence of a corresponding grade of acuteness of the disease. It may be laid down as a fact applicable to inflammatory diseases in general, that the symptoms distinguished as constitutional have no fixed relation to the extent or intensity of the local affection; in other words, the same amount of acute pleuritis will give rise in one person to more, and in another person to less, than the average amount of constitutional disturbance.

Cough is usually present, but sometimes wanting. The pain in coughing leads instinctively to efforts to repress it, and this gives to the mode of coughing a character denoted by the term suppressed. The patient succeeds, to a certain extent, in these efforts. The expectoration is slight or wanting, and, when present, it consists of simple mucus. The exceptions to this rule are the cases in which the development of pleuritis is preceded by bronchitis. When these affections are associated, it is merely a coincidence; there is no tendency in either to give rise to the other.

The respirations are increased in frequency, but not greatly. Their increased frequency at this period is due to the arrest of the inspiration, before it is completed, in consequence of pain. The patient instinctively multiplies the respiratory acts to compensate for the want of a full inspiration. As a rule, the patient in lying chooses a position on the healthy side, the weight of the body upon the affected side increasing the pain and soreness. This rule is by no means without exceptions. Not unfrequently the decubitus is either dorsal or diagonal.

These symptoms constitute the clinical history of this disease during the first stage, or prior to liquid effusion. They continue into the second stage, but, after a certain amount of effusion has taken place, they are materially modified. The pain is notably lessened, and may disappear, except on forced breathing. The acts of coughing are less painful, and

the efforts at suppression are less apparent. The febrile movement diminishes, and may even cease during this stage. Other evidences of constitutional disturbance are less marked. The patient reports better, and may be able to sit up and perhaps walk about the room. The respirations are more or less frequent; their frequency now depends on the compression of the lung by liquid. Their frequency will be great, other things being equal, in proportion to the quantity of liquid and the rapidity of the effusion. If a considerable amount of the liquid be rapidly effused, the respirations are rapid, the patient suffers from a painful sense of the want of breath, or dyspnœa, and may be obliged to maintain the sitting posture. If the quantity be not large, and the effusion have not taken place rapidly, the patient will not be likely to suffer from dyspnœa while remaining quiet; but exertion will cause panting and a sense of the want of breath. Even with the pleural sac distended with liquid, the only effect on the breathing may be an increase of the frequency of the acts to twenty-five or thirty per minute, without suffering so long as the patient remains quiet. The diminution or cessation of pain is due to the restrained movements of the pleural surfaces upon each other, in consequence of the presence of the liquid and lymph, the latter perhaps agglutinating the portions of these surfaces which are in contact. The change as regards febrile movement and other constitutional symptoms, proceeds, in part, from the removal of the conditions causing pain, and, partly, because, after exudation has taken place, the disease is mitigated from an intrinsic tendency to decrease. The patient now, as a rule, prefers to lie upon the affected rather than the healthy side, as in this position he is able to expand more freely the opposite lung. To this rule, however, there are exceptions; and the decubitus in this stage, as in the first stage, is frequently either dorsal or diagonal.

During the stage of absorption, pain is either wanting or produced only by muscular efforts; febrile movement has disappeared; cough diminishes or ceases; the respirations become less and less frequent, and are less hurried by exercise; the appetite and digestion return, and the normal condition of all the functions is gradually restored. During this stage the patient is convalescent; he is able to be out of doors, and, perhaps, to resume in part his usual avocation and habits. Convalescence is declared, and the symptoms, both general and local, may appear to denote that recovery has taken place, while some liquid effusion still remains; the lymph is not yet fully absorbed, and the formation of new tissue leading to permanent adhesions is going on. A sense of weakness in the affected side, together with some soreness or pain on unusual exertions, frequently continues for some time after the termination of the career of the disease.

Primary or idiopathic pleuritis, as already stated, affects, more or less, an entire pleural membrane; it is general, not partial nor circumscribed. If it be partial or circumscribed, it is developed as a complication of some other pulmonary affection, as a rule. It will be seen hereafter that it occurs as a complication of pneumonitis and phthisis, but it is generally, under these circumstances, subacute. Primary pleuritis does not lead to the development of pneumonitis, except that the air-cells in immediate proximity to the pleura are sometimes involved; nor does it involve any tendency to bronchitis. It is a unilateral disease, that is, it affects the pleura of one side only. The exceptions to this rule are so unfrequent, that the disease, when bilateral, or double, may be presumed to be secondary to another pulmonary affection, generally tuberculosis. I have met with a case of double pleuritis, accompanied with a large effusion into both

pleural cavities. Death took place by apnœa, in this case, and pleuritis was found to be consecutive to a small tuberculous deposit in both lungs. Such cases are extremely rare.

Pathological Character. — The disease under consideration is an example of acute inflammation affecting a serous membrane. Inflammation is an elementary form of disease. Its phenomena and results are the same essentially whenever it affects a serous membrane. In different situations it has points of difference, relating to the structure affected, and it presents diverse modifications dependent on other circumstances than its seat. Nevertheless, there are features common to acute inflammation wherever seated, and under all circumstances, sufficient to show the form of disease to be essentially the same. The phenomena of inflammation are best studied when it is situated externally, or in parts accessible to observation during life. It is therefore considered at length in treatises on surgical pathology and surgical diseases, to which the reader is referred for a full account of events which will be here very briefly noticed.

The sensible changes which first occur in an inflamed part are incident to hyperæmia, or a morbid accumulation of blood in the part. Hence arise redness, heat, pain, and swelling, the four characters which have heretofore entered into the definition of inflammation. The accumulation of blood is a result of an undue determination of blood to the part; in other words, the part receives a larger amount of arterial blood than in health. There is also a retardation of the circulation through the inflamed part. So far, the condition is expressed by the term active congestion, called by Virchow fluxion. If the affection should go no further, there would hardly be sufficient evidence that inflammation has become developed, or it might be considered as incipient inflammation disappearing by delitescence. But inflammation rarely ceases at this incipient period. A variety of local events may follow, some of which always occur, different cases presenting very wide differences arising from the presence of some of the events and the absence of others. Of the local events succeeding to active congestion, one is death of the part. Complete stasis of the circulation may occur, and the affected part loses its vitality; it becomes gangrenous or sphacelated, and will slough away, if the life of the patient be sufficiently prolonged. This is a rare occurrence in pleuritis and other serous inflammations. The escape of liquor sanguinis or blood-plasma is another event occurring constantly in serous inflammations, also in certain parenchymatous inflammations, and, exceptionally, in inflammation of mucous membranes. Coagulated fibrin, or lymph, is a characteristic product of inflammation. Another product, in like manner characteristic, is pus. The production of adventitious tissue is another event, the occurrence of which is illustrated by the morbid anatomy of pleuritis. This event occurs, as a rule, in serous inflammations. Extravasation of blood is an occasional event incidental to inflammation in various situations. Other events are, softening of the structures affected, induration from the presence of lymph, ulceration, thickening, etc. These different events, belonging to the natural history of inflammation, will be referred to frequently in connection with the anatomical characters of different individual inflammatory diseases.

Waiving consideration of the historical events just enumerated, the inquiry arises, in what consists the local deviations from health which constitute inflammation? in other words, what is known of its essential nature? Reverting to the fact already stated, that the first appreciable change is an abnormal determination of blood, the answer to the foregoing

inquiry involves an explanation of this fact. Why is more blood determined to an inflamed part than in health? We might answer this question satisfactorily, if the causes determining the quantity of blood which each organ and structure contains in health were known. The amount of blood which a part receives in health is by no means exclusively regulated by the forces which carry on the general circulation, and which chiefly belong to the heart. Parts receive more or less blood according to their state as regards functional activity. The stomach, for example, receives a much larger quantity of blood during the act of digestion than at other times. A very striking contrast, in this respect, is offered by the uterus before and after impregnation. The explanation of the cause or causes determining thus, in health, within certain limits, the amount of blood which different parts receive, devolves on the physiologist; and when this is understood, the pathologist may be able to explain why there is hyperæmia in an inflamed part. With our present knowledge, two explanations are offered. One of these attributes to each part an inherent attractive force between the blood and the tissues. The physiological operation of this force regulates the quantity of blood in different parts in health, and a morbid exaggeration of the force accounts for an overplus of blood in the congestive stage of inflammation. The other explanation relates to the vessels and the vaso-motor nerves. The regulation, in health, of the quantity of blood in parts being considered as due, measurably, to differences with respect to the contraction and relaxation of the vessels, hyperæmia is attributed to relaxation from paralysis, and, on the other hand, a morbid deficiency of blood, or local anæmia, to contraction from spasm. Whichever of these two explanations be accepted, or, assuming each to be more or less involved, it is evident that to account for an increased quantity of blood in an inflamed part, is only to take one step, however important it may be, in the pathology of inflammation. Most of the events following the accumulation of blood in inflamed parts denote aberration of the molecular changes involved in nutrition. Inflammation, therefore, consists, in great part, of perversions of nutrition; and when the physiologist is able to explain the local changes belonging to healthy nutrition, the pathologist may be able to explain the perversions which belong to inflammation. In conclusion, then, we may say that inflammation is a morbid deviation from those conditions of health which relate to the circulation and nutrition of the part affected.

After the foregoing brief account of inflammation, it will suffice, in treating of other inflammatory affections, to indicate, under the head of pathological character, the points which distinguish this elementary form of disease in the particular affection under consideration.

Causation.—Acute pleuritis may be produced traumatically by contusions, especially if accompanied with fracture of the ribs, and by penetrating wounds. It is remarkable, however, that severe injuries of the chest often occur without giving rise to general pleuritis. Persons receiving gunshot wounds frequently escape if the ball or other foreign material be not lodged within the pleural sac. The disease is attributed, in certain cases, to the action of cold. This has so long been considered as a frequent source of a great number of diseases, that patients at once are led to refer an attack to some exposure, often, doubtless, when it had no causative agency, or, at most, acted only as an exciting cause. Still it is probable that the disease sometimes originates in this way. In the larger proportion of the cases in which it is not traumatic, it is spontaneous, that is, it proceeds from an unknown internal cause. It occurs sufficiently often

in persons affected with the diseases of the kidneys embraced under the name Bright's disease, to show a pathological connection; and in these cases it is referable to the accumulation of urea in the blood. It is developed occasionally in connection with acute articular rheumatism. It is an occasional sequel or concomitant of scarlatina, measles, and continued fever. It enters into the history of pyæmia and of septicæmia.

The liability to the disease is not equal at all periods of life. The disease is extremely rare in infancy. It is not uncommon in childhood. It occurs in youth and middle life much more frequently than in old age. It is as rare in old age as in infancy. The proportion of males over females, among cases of this disease, vastly preponderates. There do not appear to be any causative influences pertaining to constitution, season, climate, or locality. The acute variety of pleuritis is not of very frequent occurrence; the subacute or chronic variety, in my experience, is much more frequently met with. It is less frequent than pneumonitis, and, in relative frequency, bears no comparison with acute bronchitis.

Diagnosis.—Although the symptoms which enter into the clinical history of acute pleuritis are sufficiently characteristic to point to the existence of the disease, they are not, singly or collectively, sufficient for the diagnosis in all cases. The characteristic pain is not peculiar to the disease. This occurs in some cases of intercostal neuralgia and pleurodynia as strongly marked as in acute pleuritis; and these three affections have heretofore been often confounded in practice. Moreover, the pleuritic pain in some cases of pneumonitis is as intense as when the pleuritis is a primary disease, and the former disease has not infrequently been mistaken for the latter. On the other hand, acute pleuritis is liable to be overlooked in the cases in which pain is slight or wanting. More or less febrile movement is present in acute pleuritis, but this symptom may accidentally be associated with intercostal neuralgia; it will be likely to be present in pleurodynia, and it exists, of course, in pneumonitis. The diagnosis is to be based on the physical signs, taken in connection with the symptoms. The latter are of importance, and, indeed, essential in determining whether the affection be acute or not. The differential diagnosis consists in discriminating between the disease under consideration and intercostal neuralgia, pleurodynia, and pneumonitis.

The diagnosis in the first stage, with the aid of physical signs, cannot always be made with positiveness. Examination of the chest by inspection will show restrained movements on the side to which the pain is referred; on percussion, there will be found to be no distinct disparity between the two sides, and on auscultation, the murmur of respiration will be more or less weakened on the affected side. But these signs are due to the fact that the pain leads instinctively to a diminished use of the lung on the side affected, while the use of the other lung is increased. These signs are equally present when the pain is incident to the affections from which this disease is to be discriminated. A slight friction murmur may be discovered in this stage; if distinctly present, its diagnostic significance is important; it shows that pleuritis exists, and the discrimination then lies between pleuritis as a primary disease or as a complication of pneumonitis. To decide this point at once is not always easy. The diagnostic sign of pneumonitis, viz., the crepitant rale, if present, settles the question; but as this sign is by no means present uniformly in pneumonitis, its absence does not authorize the exclusion of that disease. The same remark is applicable to the characteristic expectoration of pneumonitis. It must be confessed that, in a certain number of cases, this differential diagnosis

requires a little delay. But a friction murmur is heard in only a very small proportion of cases during the first stage, and, in the absence of this sign, the signs belonging to the second stage are essential to render the diagnosis positive.

The signs belonging to the second stage are usually present without much delay. If the disease be idiopathic pleuritis, after the lapse of twelve or twenty-four hours, liquid effusion will have taken place in sufficient quantity to be apparent. The signs now denoting the existence of the disease are those due to liquid effusion. The diagnosis is based upon these signs, in conjunction with the symptoms and history, and on the absence of the signs of pneumonitis.

The signs of liquid effusion are obtained by percussion, auscultation, palpation, and inspection. On percussion, dulness or flatness is found at the base of the chest, extending upward in proportion to the quantity of liquid, the patient being in a sitting posture. By the finger which serves as a pleximeter, also, is perceived an increased sense of resistance on percussion. The upper limit of the dulness or flatness corresponds to a horizontal line drawn across the anterior and lateral surface of the chest, this line denoting the level of the liquid. Changing the position of the patient to recumbency on the back, frequently induces a marked change in the relation of dulness or flatness and the resonance, as previously determined on the anterior surface of the chest, in the sitting posture; the liquid gravitating to the posterior part of the chest, the lung descends in front, and furnishes resonance for a greater or less distance below the line which was coincident with the level of the liquid while the patient was sitting. This latter test of the presence of liquid is not available in all cases. If the pleural surfaces above the level of the liquid be united by old adhesions, or aglutinated by lymph, the liquid and lung will maintain the same relation in different positions of the body. The failure of this test, therefore, is not proof against the presence of liquid. The test, however, is available, according to my experience, in a large majority of cases. The resonance over the lung above the level of the liquid, if the latter rise to a third, a half, or, perhaps, over two-thirds the height of the chest, is exaggerated, and acquires, in part, a tympanitic quality, constituting vesiculo-tympanitic resonance.

On auscultation, the respiratory murmur is either suppressed or feebly appreciable below the level of the liquid. Above the liquid, it is usually weak, as compared with the murmur on the opposite side. If the lung be considerably reduced in volume by the amount of liquid, the respiratory sound will become broncho-vesicular, or rude, and the vocal resonance will be increased. If the liquid be sufficient to compress the lung into a solid mass, the latter will furnish the bronchial respiration. The bronchial respiration will be heard over the site of the compressed lung. It is usually limited to that site, but, in a certain proportion of cases, it is diffused over the greater part or the whole of the affected side. The normal vocal resonance is either suppressed or diminished over that portion of the affected side which corresponds to the space occupied by the liquid. But if the accumulation of liquid be large, bronchophony may be produced over the whole of the compressed lung, or at the portion in contact with the liquid. The bronchophony has sometimes a tremulous or bleating character, and is then ægophony. If the chest be filled with liquid, bronchophony is sometimes diffused over the whole of the affected side.

Vocal fremitus is either arrested or diminished by liquid effusion. From this fact is derived valuable evidence of the presence of liquid when the effusion is in the right pleural cavity, in consequence of the greater amount

of fremitus over the right side in health. If the question be as to the presence of liquid in the right pleural cavity, and the fremitus be found to be greater on the left than on the right side, the evidence of liquid is strong.

If the quantity of liquid be large enough to distend the pleural sac, the intercostal depressions may be diminished or destroyed at the inferior, anterior, and lateral portions of the chest. This constitutes valuable evidence of the presence of liquid.

Other and marked signs of effusion are present if the quantity of liquid be sufficient to dilate the chest. This occurs exceptionally in acute pleuritis. It occurs much oftener in the chronic variety of the disease, and the signs referred to will be noticed in connection with the diagnosis of the latter.

The physical signs not only lead to a positive diagnosis after the first stage, but they show the amount of liquid in the pleural sac, a point of importance with reference to treatment. By means of daily explorations, the physician may ascertain whether the effusion be increasing or diminishing, and the rate of either the increase or diminution. The information thus obtained is highly important as a guide to the employment of therapeutical measures. This information cannot be obtained from the symptoms. The signs, therefore, are essential, not only to the diagnosis, but to a proper knowledge of the progress of the disease.

After absorption, to a greater or less extent, of the liquid, the pleural surfaces coming into contact over a larger area, and roughened by lymph which has now become dense and closely adherent, a friction murmur is frequently apparent. This is sometimes so loud as to be heard by the patient. It may continue into convalescence, ceasing when the pleural surfaces have become united by means of newly-formed tissue. A friction murmur, however, by no means occurs uniformly even at this stage of the disease.

Prognosis.—The prognosis in cases of acute, idiopathic, simple pleuritis is always favorable, provided the disease be uncomplicated, and the constitution of the patient be not enfeebled. There is reason to believe that, without therapeutical interference, it would very rarely prove fatal. I have collected several cases in which the disease passed through its course favorably without any treatment. It may possibly prove fatal in consequence of a large amount of liquid effusion occurring very rapidly, death taking place by apnœa. I have known one instance in which the loss of a hospital patient, suddenly and unexpectedly, seemed fairly attributable to the fact that the pleural sac was greatly distended with liquid. Developed as a sequel to other diseases, or in the course of a grave affection, such as Bright's disease of the kidneys, or in persons with broken constitutions, it may destroy life by asthenia. Acute pericarditis is sometimes developed simultaneously with, or during the progress of, pleuritis, and these associated diseases are apt to prove fatal. Their occasional coincidence is to be borne in mind, or the pericarditis, in this connection, if not carefully sought for, will be likely to be overlooked. As already stated, the development of pneumonitis, consecutively to pleuritis, is not to be expected, nor is there much, if any, danger that an acute pleuritis, after its development, will eventuate in suppuration, constituting the variety of the disease called empyema. In short, the intrinsic tendency of the disease is to recovery, a fatal termination being due very rarely to the disease *per se*, but to extrinsic circumstances.

CHAPTER II.

Treatment of Acute Pleuritis—Measures indicated in the First Stage—General Considerations relating to Bloodletting in Acute Inflammations—The use of Opium in Acute Pleuritis and other Acute Inflammations—Measures indicated in the Second and the Third Stage of Acute Pleuritis.

THE objects of treatment in acute pleuritis differ in its different stages, and the latter, therefore, claim, severally, distinct consideration with reference to therapeutic indications. The objects in the first stage are to arrest, if possible, the progress of the disease, to diminish its intensity, if it be not arrested, to limit the amount of morbid products, and to relieve suffering; in other words, the treatment relates to the employment of abortive, curative, and palliative measures. The indications in the first stage of this disease are essentially the same as in the early period of most acute inflammations. The general principles which should govern the treatment in this stage, therefore, will be here considered, and simply referred to hereafter in connection with other diseases to which they are measurably applied.

Owing to its brief duration, patients are frequently not seen until this stage has passed. Can the disease be arrested at this stage if the opportunity offer and a positive diagnosis be made? Admitting that, formerly, physicians did sometimes succeed, as they believed, in cutting short the disease, it must be said, in answer to this question, that there are no known means which can be relied upon for this end. Bloodletting, and other so-called antiphlogistic measures, which were formerly employed for this object, have certainly not been successful in a sufficient number of cases to warrant their employment to an extent which will render them likely to do harm if they are not successful. Assuming that the disease goes on to the second stage, the question then is, what curative and palliative measures are to be employed? This question leads at once to the consideration of bloodletting.

A great change has taken place, within the last few years, with respect to bloodletting in the treatment of acute inflammations. This measure was formerly thought to be highly important, and was rarely omitted. It is now considered by many as seldom, if ever, called for. The infrequent use of the lancet now, contrasted with its frequent use forty years ago, constitutes one of the most striking of the changes in the practice of medicine which have occurred during this period. It can hardly be doubted that this measure was formerly adopted too indiscriminately, and often employed too largely; but, the natural tendency being to pass from one extreme to another, the utility of bloodletting in certain cases, at the present time, is not sufficiently appreciated.

Experience and pathological reasoning combine to show that bloodletting does not exert a direct controlling effect upon an inflammatory disease. It may exert a powerful immediate effect as a palliative measure, but whatever curative power it may possess is exerted indirectly. Its therapeutic action, in general, consists in lessening the frequency and force of the heart's action; in other words, in diminishing the intensity of symptomatic fever. In the early period of an acute inflammation accom-

panied by high febrile movement, as indicated by a pulse accelerated and of abnormal strength, the abstraction of blood affords relief, and may contribute to a favorable progress of the disease. It should enter into the treatment of a certain proportion of cases, provided other and more conservative means for the same ends are not available.

The evils of bloodletting arise from its spoliative effect upon the blood. It diminishes the red globules, and these, during the progress of an acute disease, are not readily reproduced. It induces, thus, the anæmic condition, and in this way impairs the vital powers. It will be likely to do harm, therefore, whenever it is important to economize the powers of life, and it may contribute to a fatal result in diseases, or cases of disease, which involve danger of death by asthenia.

The useful effects of bloodletting may frequently, if not generally, be obtained by other means which require less circumspection in their employment, because, if injudiciously resorted to, they are in a less degree hurtful. The mass of blood may be temporarily lessened by saline purgatives and diaphoretic remedies, conjoined with a restricted ingestion of food and liquids. Depletion is obtained in this way without spoliation or impoverishment of the blood. The frequency of the heart's action may be affected by nauseant sedatives, such as tartar-emetic, ipecacuanha, etc., and by direct sedatives, viz., digitalis, aconite, and the veratrum viride. By saline depletories and sedatives, the symptomatic fever may be modified without the expenditure of blood, and thus the evils of bloodletting avoided. The advantage of bloodletting consists mainly in the promptness of its operation. Several hours are required to secure results from the means employed in lieu of bloodletting, whereas, the effects of the latter are produced in a few moments.

In accordance with these views, bloodletting is never indicated by the fact simply that acute inflammation exists; it is a measure directed, not to the disease *per se*, but to circumstances associated with the disease. The state of the circulation, and other circumstances, furnish the indications for the employment of this measure. It is admissible, if, with the development of inflammation, there exist high symptomatic fever, the patient being robust and in good health when attacked, and the disease not involving danger of death by asthenia. The measure is admissible, under the conditions just stated, whenever the promptness with which its effects are obtained renders it desirable to adopt it in preference to other measures producing the same effects with more or less delay. *Per contra*, bloodletting is not admissible when the development of inflammation is not accompanied by high symptomatic fever, when the patient was not in good health when attacked, nor when the constitution is feeble, nor when the disease involves danger of death by asthenia. These rules of practice, while they accord to bloodletting therapeutic value, undoubtedly restrict its use within narrow limits.

Applying these rules to the disease under consideration, a patient in the first stage of acute pleuritis, robust, perhaps plethoric, suffering from severe pain and a sense of oppression, with a strong, non-compressible pulse, will derive immediate relief from the abstraction of from ten to sixteen ounces of blood. The loss of this quantity of blood, under such circumstances, in a disease like this which does not tend to destroy life by asthenia, will give rise to no evil results, but will be likely to affect favorably the progress of the disease. On the other hand, a patient feeble, or anæmic, with a pulse more or less frequent, but denoting diminished power of the heart's action, should not be bled, notwithstanding the local symptoms would undoubtedly be thereby relieved. By impairing the

vital powers, the loss of blood will do harm, and is not admissible under these circumstances merely as a palliative remedy. And, in the first case, if the local symptoms do not urgently call for immediate relief, other measures may be substituted for the bloodletting.

Before leaving the consideration of bloodletting, several incidental points may be briefly noticed.

This measure is perhaps more applicable to the treatment of inflammation affecting the pulmonary organs than to the treatment of other inflammatory affections, in consequence of the relations of the former to the circulation. The free passage of the blood through the pulmonary circuit seems to be promoted, and the functional labor which the lungs have to perform is diminished by the abstraction of blood. At all events, relief of the sense of oppression and dyspnœa attendant on the early stage of acute inflammation of any of the pulmonary structures is more quickly and effectually procured by bloodletting than by other measures. Were it not for its ulterior effects, it would be invaluable as a palliative measure in pleuritis and other inflammatory affections within the chest.

In another mode the abstraction of blood may sometimes be peculiarly useful in affections of the lungs involving considerable or great obstruction to the passage of blood through the pulmonary circuit. This obstruction occasions an accumulation of blood within the cavities of the right side of the heart; hence, congestion of the systemic veins, giving rise, if sufficient in degree, to lividity or cyanosis. The accumulation of blood in the cavities of the right side of the heart, under these circumstances, weakens the force with which the ventricle and auricle contract, and paralysis of this portion of the heart from over-distension may follow. The formation of a heart-clot may be a consequence of this accumulation. In certain cases, bloodletting may be advisable with a view to diminish the accumulation of blood in the cavities of the right side of the heart; but it is to be employed for that end only when the contraindications which have been mentioned are not present.

After bloodletting, the pulse sometimes appears to indicate increased power of the heart's action. The artery seems to strike against the finger with more force than before the abstraction of blood. Formerly practitioners were misled by this effect upon the pulse, and bloodletting was employed as a means of increasing the power of the heart's action. The sensation which the finger receives, in these cases, is delusive, and is caused by the quickness of the movements of the artery. This has been shown by the sphygmograph to depend on the diminished tension of the arteries following the abstraction of blood. It is to be borne in mind, in estimating the power of the heart's action by the sensible characters of the pulse, that the sense of resistance which is felt and the amount of pressure required to compress the artery are the evidences of strength.

To a certain extent the advantages of bloodletting, inclusive of the promptness of its operation, may be obtained by arresting temporarily or retarding the circulation in a part more or less remote from the seat of the inflammation. A ligature applied to one or more of the extremities will effect this object; so, also, will the removal of atmospheric pressure over a considerable space. There is reason to think that these measures as substitutes for bloodletting have not been sufficiently considered. It is probably owing to their effect in withdrawing temporarily a certain quantity of blood from the circulation, that dry cups and various so-called revulsive applications to the surface of the body, are of utility in the first stage of acute inflammation.

The evils of indiscriminate and excessive bloodletting are manifested

by a larger rate of mortality in those diseases which tend to destroy life by asthenia, and it can hardly be doubted that the death-rate has been diminished by a much more sparing use of the lancet within late years. But the results of injudicious bloodletting are manifested in cases which end in recovery, as well as in those which end fatally. These results consist in protracted convalescence and subsequent feebleness. The cases of different inflammations treated formerly by bloodletting with other measures entering into the so-called antiphlogistic method, and the cases now treated otherwise, present a striking contrast as regards the condition of patients during convalescence and after recovery.

The opinion held by some that diseases have undergone a notable change within the memory of those now living has been already referred to.[1] They who hold this opinion suppose that bloodletting and other antiphlogistic measures are less appropriate now than formerly in consequence of such a change. With a professional experience of nearly forty years, I do not hesitate to express a conviction that acute inflammations at the present day are essentially the same as they were as far back as the time just named, and that antiphlogistic measures were neither more nor less appropriate then than now.

In addition to general bloodletting, or the employment of venesection, much importance was formerly attached to the abstraction of blood by cups or leeches applied in the neighborhood of the inflamed part. Local bloodletting, in some cases, is more convenient than general; but, so far as the abstraction of blood is concerned, it is difficult to conceive that it is a matter of much importance from what part of the body or vascular system it is taken. Whether it be abstracted by means of cups, leeches, or the lancet, the benefit or injury will depend on the quantity withdrawn in a given period. Whatever advantage may accrue from the removal of a certain amount of blood by cups or leeches, over the abstraction of the same amount by venesection, must be derived from the operation of the former as revulsive measures.

With these remarks, leaving the consideration of bloodletting, and reverting to the question concerning the curative and palliative measures to be employed in the first stage of acute pleuritis, we are led to the consideration of opium. And, with respect to this remedy, certain considerations may here be presented, which will apply to the treatment of other inflammations.

A great change has taken place, within the last few years, with respect to the use of opium in acute inflammations. It was formerly used with much reserve, under the apprehension that, acting as a stimulant, its influence upon the local disease must be unfavorable. It was regarded as antagonistical to the antiphlogistic plan of treatment. Clinical experience and sounder pathological views, however, have led to the knowledge of its great value in the treatment of inflammatory affections wherever situated. It is valuable, not alone as a palliative, but as a curative remedy. Its palliative efficacy is, of course, intelligible; and we can also, to some extent, understand its curative influence. By relieving pain, it diminishes the determination of blood to the inflamed part, for pain is alone sufficient to occasion an increased afflux of blood to a part. This fact is illustrated by cases of neuralgia affecting a superficial nerve. Neuralgia of the supra-orbital nerve, for example, occasions a determination of blood to the conjunctiva, so that this membrane appears to be inflamed, and the congestion disappears directly the pain is relieved by a full opiate. Opium

Vide page 132.

exerts also a curative influence by preventing or diminishing the constitutional disturbance which inflammations are apt to occasion; it places the system in a condition to tolerate better the local affection. The severity of an inflammatory disease depends much on the amount of constitutional disturbance which it occasions, and, with respect to the latter, different cases differ widely, although in each the degree and extent of the local affection be the same. Life is often destroyed, not in consequence of the injury done to the inflamed part, but because the vital powers are inadequate to bear the continuance of the disease. These considerations afford some insight into the utility of opium, especially when patients are of the class who are liable to take this remedy without inconvenience, there being, as is well known, a great difference among different persons in this regard. The evidence of the curative value of opium, of course, is derived from experience, and there is ample ground for the belief that, by its judicious use in acute inflammations, not only is their course divested of much of the suffering which would otherwise be experienced, but their intensity is lessened, and the danger of death diminished in those inflammations which tend to destroy life by asthenia. The immediate effect of this remedy is often very strikingly manifest in improvement as regards the local and general symptoms.

Considering now the use of opium in the first stage of acute pleuritis, after the abstraction of blood, if this be deemed advisable, or, after a saline purgative, if this be employed in lieu of bloodletting, it will generally be judicious to prescribe opium,[1] in some form, in doses sufficient to relieve pain, and place the system fairly under an anodyne influence. If the pain be severe, and the constitutional disturbance considerable, the use of opium need not be delayed for the operation of a purgative, but may be at once entered upon. This is, perhaps, the most judicious course in the majority of cases, a purgative being deferred until a distinct anodyne impression has been produced and maintained for some hours by opium. Conjoined with the use of opium, sedative remedies, addressed to the circulation, may be employed. These should not be pushed to the extent of producing disorder. If, for example, tartar-emetic be given, it should not be carried beyond the point of slight nausea; and the veratrum viride, if given, should occasion no appreciable effects beyond a reduction of the frequency of the heart's action. These remedies, it is to be borne in mind, are addressed, not to the disease *per se*, but to the symptomatic phenomena of the disease, viz., those belonging to the febrile movement. As a rule, digitalis and aconite are to be preferred to the sedatives just named, because their sedative effect upon the circulation is produced without depression.

Aconite is a most valuable sedative remedy in the early stage of this, as of other acute inflammations. The most effective mode of administration in order to secure promptly and fully its remedial effect, is that recommended by Ringer, namely, half a drop, or a drop, of the tincture to be given every ten minutes, or quarter of an hour, for two hours, and afterwards the dose repeated hourly. Smaller doses are to be given if the pulse become feeble, or there be much prostration.

A summary of the treatment of the first stage of acute pleuritis, then, will embrace, bloodletting in some cases, the use of opium given sufficiently to relieve pain and tranquillize the system, a saline purgative, and remedies designed to act as sedatives upon the circulation. Blisters should

[1] The word opium is here used as a general term, including the alkaloids, morphia, and codeia.

not be applied in this stage. They occasion general disturbance more than enough to counterbalance any effect by way of revulsion or substitution. They add an inflammation of the skin to the existing inflammation of the pleura. A sinapism, turpentine stupes, or fomentations to the chest, will secure all the benefit of vesication without the annoyance and other evils of the latter. Moreover, a blister is an obstacle in the way of those examinations of the chest which are of importance as affording the only reliable information respecting the progress of the disease. Niemeyer advocates, as a palliative measure safe and efficient, the application of cold water over the affected side of the chest, the application being made by means of napkins dipped in cold water, which are to be renewed every five minutes. He states that the pain is promptly relieved by this measure. The application of cold water over the whole surface of the body, either by means of the bath, or by wrapping the body in a wet sheet, employing, in short, cold water with a view to diminish the heat of the body, has been recommended by other clinical observers as perfectly safe, and, under judicious management, useful in this and other acute inflammatory affections. For a fuller account of this measure, the reader is referred to the treatment of typhoid fever. Employed as an antipyretic measure, it is indicated only by a considerable elevation of temperature, as shown by the thermometer in the axilla. The immediate favorable effect is shown by decline of temperature, diminished frequency of the pulse, and improvement in other respects. If the immediate effect be thus favorable, the measure may be repeated, at intervals, whenever the fever again becomes high, as shown by the axillary temperature and the pulse. Dry cups applied to the chest often afford prompt and marked relief of the pain and dyspnœa in the first stage of acute pleuritis, as well as in other pulmonary affections accompanied by these symptoms singly or combined. Preventing the respiratory movements of the chest on the affected side by means of long strips of adhesive plaster encircling this side and extending partially over the side not affected, affords notable relief of the lancinating pain felt in the acts of inspiration.

In the second stage, so long as the quantity of liquid effusion is small and a further accumulation may be expected to take place, the indications belonging to the first stage may continue. If the pain be still acute and the febrile movement have not abated, measures to relieve the former and lessen the latter are indicated. Bloodletting is rarely called for, but depletion by purgatives may be useful, not only by lessening the febrile movement, but by restraining the amount of effusion. Diaphoretic remedies are useful by contributing to the two ends just stated. Opium is indicated in proportion to the pain and constitutional disturbance, and sedative remedies addressed to the circulation may be employed.

These measures cease to be appropriate when considerable effusion of liquid has taken place, when pain is no longer a prominent symptom, and the febrile movement has either ceased or become much diminished. The object of treatment now is to promote absorption of the effused liquid. The means which may be employed for this object are, hydragogue purgatives, diuretics, blisters, and the use of certain remedies which have been supposed to act directly as sorbefacients.

Hydragogue purgatives act most promptly and efficiently. The more active hydragogues, which are drastic in their operation, should be given circumspectly, and generally need not be employed. Reference is had to such remedies as elaterium and gamboge. The saline purgatives, such as the bitartrate of potassa, the citrate or sulphate of magnesia, are to be

preferred as sufficiently effective and less severe. These will sometimes effect a rapid decrease of the liquid.

Diuretics are sometimes equally but less rapidly effective. They effect the object with less disturbance of the system and are less debilitating. The union of several diuretic remedies is more likely to prove effective than a single remedy of this class. The squill and digitalis may be combined, and, in addition, the diuretic salts of potassa, or the iodide of potassium, may be given dissolved in an infusion of some one of the various vegetable diuretics. The mustard whey is a favorite remedy of my colleague, Prof. McCready, and I have found it to act upon the kidneys sufficiently.

The regulation of the amount of drink ingested is an important point with reference to the promotion of absorption. The elimination of water by the bowels or kidneys is of little avail if the patient be allowed to take fluids into the system abundantly. The quantity of liquid ingested should be as small as is compatible with comfort. The treatment is often rendered inefficient by inattention to this point.

Blisters, in this stage of the disease, doubtless contribute to the object under consideration. If the other means are effective, however, they may be dispensed with. Their interference with examinations of the chest is a matter of considerable consequence, and the annoyance which they frequently occasion is not an inconsiderable objection. If employed, small blisters successively applied in different situations, removed as soon as vesication commences, the vesicated surfaces being allowed to dry up rapidly, accomplish all the good to be effected in this way, with the smallest amount of inconvenience both to the physician and patient.

The remedies supposed to act as sorbefacients are mercury and iodine. Mercury I have long ceased to employ for this end. Of doubtful efficacy, the annoyance and other evils incident to mercurialization render it objectionable. The efficacy of iodine is, perhaps, equally doubtful, but it is not open to similar objections. It may be given internally, or applied externally in the form of either the ointment or tincture.

It is an important injunction not to continue perturbatory measures with a view to promote absorption too long, nor to push their use too far. The decrease of liquid effusion, after it has reached a certain point, is apt to go on slowly, for reasons already stated. Whenever this point is reached, cathartics and diuretics should be discontinued, or employed with great moderation, else they will be likely to do harm, rather than good, by weakening the patient. And if, at any time, these measures appear to impair the general condition, the propriety of continuing them is doubtful. A leading object in the second stage of the disease is to maintain the constitutional strength. For this object the diet should be nutritious; tonic remedies are useful, and a little wine or spirit may be allowed. These measures should constitute the treatment, after those designed to promote absorption have been sufficiently carried out, and should take the place of the latter whenever there is evidence of the strength giving way.

It is very rarely the case that this disease tends to a fatal ending by asthenia. Should such a tendency be manifested by the symptoms, viz., frequency and feebleness of the pulse, muscular prostration, etc., the measures which constitute the supporting treatment are of course indicated. These measures, which form the most important part of the treatment of the diseases involving danger by asthenia, consist of alcoholic stimulants, nutritious alimentation, and tonic remedies. They will be noticed more fully in connection with diseases in the treatment of which they are oftener called for.

A fatal result in acute pleuritis may be due to rapid and excessive effusion of liquid, as already stated. If the liquid accumulate sufficiently to endanger life, it should be at once withdrawn from the chest by the operation of thoracentesis. This operation is much more frequently indicated in chronic pleuritis, and will be considered in connection with the latter variety of the disease.

The measures which have reference to the promotion of absorption may be indicated in the third stage; that is, for a certain period during the progress of absorption. When these measures have been carried to a sufficient extent, and the amount of liquid is considerably reduced, the patient is to be considered as convalescent. During convalescence the object is to re-establish the normal health of the patient. This is to be done by tonic remedies, a nutritious diet, and other hygienic means. Solid food, embracing a fair proportion of meat, may be allowed whenever taken with relish and digested. Alimentation is important; and if the appetite be small and the digestion weak, remedies to improve both are indicated. No apprehension need be felt that a diet as nutritious as can be taken without inconvenience will do any harm; on the contrary, the more nutritious the food which can be taken and digested, the more rapid the convalescence. Wine or spirit, or beer, in small quantities, taken with meals, will expedite recovery. Going out of doors and gentle exercise are to be encouraged. The patient will gain more rapidly as regards appetite, digestion, and strength, if he do not confine himself within doors; and with proper precautions, no risk of harm is incurred. The removal of the liquid which remains, the absorption of lymph, and the development of new tissue leading to adhesions, will go on rapidly in proportion to the rapidity with which improvement in the general condition takes place.

In the foregoing account of the treatment of simple acute pleuritis, it is assumed that, exclusive of a small number of cases in which this disease destroys life either by asthenia or apnœa, its course is toward convalescence, without becoming chronic. This is the rule, to which there are exceptions. If the disease become chronic, the measures of treatment indicated are those which will be considered under the head of chronic pleuritis.

The prevention of acute pleuritis hardly claims consideration. The abrupt and rapid development of the disease precludes the employment of prophylactic measures; there are no premonitions which warrant our anticipation of its occurrence.

Marked dulness on percussion over the affected side, especially at the inferior portion, may continue for some time after the liquid effusion has disappeared, the symptoms, general and local, denoting recovery, and the vesicular murmur of respiration being heard over the whole of the side. This shows that lymph remains to be absorbed, and it need occasion no apprehensions. In a patient discharged from hospital on the day these remarks are penned, the liquid effusion has nearly or quite disappeared, as shown by vesicular breathing and vocal resonance extending to the base of the chest; yet considerable dulness remains, and will probably continue for several weeks.

CHAPTER III.

VARIETIES OF PLEURITIS.

Chronic Pleuritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Prognosis—Treatment. Thoracentesis. Suppurative Pleuritis, or Empyema—Diagnosis—Prognosis—Treatment. Pleuritis with Pneumothorax—Anatomical Characters—Clinical History—Diagnosis—Prognosis—Treatment. Pneumothorax. Circumscribed Pleuritis. Hydrothorax.

OF the varieties of pleuritis, the first to be considered is the simple or ordinary chronic form of the disease. Other varieties are suppurative pleuritis, or empyema, and pleuritis with pneumothorax. Circumscribed pleuritis will claim some consideration. This chapter will be devoted to these affections, including a brief account of pneumothorax without pleuritis, and of hydrothorax.

Chronic Pleuritis.

Anatomical Characters.—The anatomical characters in simple chronic pleuritis are essentially the same as in the acute form. The pleural cavity contains serum and lymph in variable relative proportions, but, as a rule, the quantity of lymph is less, and the accumulation of liquid greater, than in acute pleuritis. Liquid effusion frequently takes place to such an extent that the affected side is more or less dilated. The lung is compressed into a small solid mass usually situated at the upper and posterior part; the thoracic walls are expanded in every direction; the intercostal spaces are pushed out to a level with the ribs or even beyond this level, and show no depression with the act of inspiration; the diaphragm may be depressed, pushing downward the abdominal organs situated in proximity to it, viz., the stomach, spleen, and liver; the lateral pressure on the mediastinum may be sufficient to move the heart from its normal situation, and, if the effusion be in the left side, the heart may be carried quite into the space belonging to the right side of the chest.

The dilatation decreases as absorption of the liquid takes place, and contraction of the affected side succeeds. This arises from the fact that the compressed lung does not readily resume its former volume when the pressure of the liquid is removed, in consequence of the layers of lymph with which it is more or less invested, and, sometimes, because pleuritic adhesions have already taken place. Other things being equal, the extent of contraction is in proportion to the amount of the previous dilatation and its duration. Usually the dimensions of the affected side in every direction are lessened, the shoulder is lowered, and lateral spinal curvature is apt to ensue. In some cases in which the lung expands to a certain point and becomes fixed by permanent adhesions at that point, the removal of the liquid below leads to a deep depression; the chest presents an appearance as if the lower ribs had been crushed inward. The contraction succeeding a large effusion is generally permanent. It becomes less marked after several months or years, in some cases, and, if the patient be quite young, it may, in the progress of time, nearly disappear. In a

patient who had chronic pleuritis with very large effusion, at the age of 17 years, followed by great contraction, I found, ten years afterwards, the two sides presenting only a slight disparity.

Clinical History.—Chronic pleuritis, in the great majority of cases, is a subacute affection from the first. Occasionally it follows the acute form of the disease. The chronic is a more frequent affection than the acute, a fact which shows that the latter does not usually precede the former, as has been stated by some authors. Of thirty-five recorded cases which I analyzed with reference to this point, in 1852, the inflammation was subacute from the first in twenty-nine. The left side is affected oftener than the right, as in acute pleuritis. Of forty-two cases, the left side was affected in twenty-three. Of seventy-eight cases analyzed by Dr. Blakison, the left side was affected in fifty-eight.

This variety of pleuritis is often developed imperceptibly, and, so far as the symptoms are concerned, is one of the most insidious and latent of diseases. It is habitually overlooked by those who do not employ the physical methods of examination. Its development is not, as in the vast majority of cases of acute pleuritis, characterized by pain. Pain is often either wanting or so slight as scarcely to attract attention. In some cases, however, the pain is moderate or considerable, but falling much short of that intensity which belongs to the acute affection. Tenderness over the chest is slight or moderate, and may be wanting.

Cough and expectoration are frequently wanting, and rarely prominent as symptoms. The cough, if present, is dry, short, hacking, and the matter of expectoration consists of mucus, transparent or slightly opaque. If there be considerable expectoration, and the matter expectorated be muco-purulent, either bronchitis coexists, or the pleuritis is associated with tuberculous disease.

The frequency of the respirations is increased, assuming the pleuritis to be accompanied by a large effusion of liquid. The increase, however, may be but moderate while the patient is at rest, but this symptom becomes marked on exercise. Deficiency of breath is also shown by inability to speak with a sustained expiration, the speech being interrupted at short intervals for a fresh inspiration. Dyspnœa is rarely present except on exercise. Here, as in acute pleuritis, the embarrassment of breathing will depend much on the rapidity with which the effusion takes place. The suppression of the respiratory function of an entire lung, in this affection, does not usually occasion lividity of the face or prolabia.

The pulse is generally more or less accelerated, ranging from 80 to 120 per minute, and it is small and compressible. There is, however, considerable variation in different cases as regards these characters of the pulse. The surface of the body frequently presents more or less capillary congestion. Sweating is apt to occur, especially during the night, and may be profuse without having been preceded by a chill or febrile movement. Irregular, slight chills, however, are not unusual, leading sometimes to the error of supposing the disease to be malarious.

The appetite is sometimes notably impaired, but in other cases it is preserved, and the digestion continues good. Diarrhœa occurs in some cases. Generally, the countenance is pallid, denoting anæmia, but this is not true of all cases; a healthy aspect is sometimes maintained. Emaciation is not usually marked, except when the disease is associated with tuberculosis. The strength is often retained in a remarkable degree. Patients are rarely obliged to take to the bed, and usually are able to be up and out of doors, even with one side of the chest filled with liquid. I

have known repeatedly persons in this condition to continue pursuits which required active muscular exertion.

This sketch of the symptomatology applies, of course, to cases of chronic pleuritis not associated with other affections furnishing symptoms which are combined with those belonging to the disease under consideration. It may be associated with pulmonary tuberculosis, but not so frequently as is stated by some writers. Indeed, in my experience, tuberculous disease has existed in a small proportion of cases only. The coexistence of this disease will be likely to render cough more prominent as a symptom, and to give rise to a more or less abundant expectoration. Emaciation and muscular feebleness will also be more marked. Pericarditis exists in a small proportion of cases. With this complication, the circulation is more disturbed, there is more suffering from dyspnœa, and the symptoms in general denote greater gravity of disease. The affection may be developed in the course of either acute albuminuria or chronic degenerative disease of the kidneys; and, under these circumstances, general dropsy may be present, emaciation and feebleness are greater, and the tendency to asthenia is more apparent. In like manner, other affections which may be associated modify and add to the symptoms pertaining to the pleuritic inflammation.

The duration is variable, but the career rarely ends under several weeks, and generally it extends over several months. As regards stages, when acute pleuritis has not preceded, cases do not come under observation until more or less liquid effusion has taken place, and, it may be, not until the pleural sac is filled with liquid. It suffices to consider the career of the disease as consisting of two stages, one embracing the period during which the liquid either is accumulating or remains stationary, and the other embracing the period during which absorption of the liquid is going on. After absorption has made a certain amount of progress, the patient may be regarded as convalescent.

Pathological Character.—Ordinary or simple chronic pleuritis is a subacute inflammation, differing from the acute form of the disease only in the degree of inflammatory action. The inflammation has no special character, but is of a low grade of intensity, with a tendency to continuance for an indefinite period.

Causation.—The same causes are involved in the causation of chronic as of acute pleuritis. It may be produced traumatically. It may sometimes be due to cold. It occurs occasionally during the course of affections of the kidneys. But, in a large majority of cases, it proceeds from internal causes which are not understood, and it is then said to be spontaneous.

An important point of inquiry relates to its pathological relations to pulmonary tuberculosis. According to some authors, it is generally consecutive to, and dependent upon, a tuberculous deposit. There has been no evidence of this in a large majority of the cases which have come under my observation. Of forty-two cases analyzed several years ago, the evidence of coexisting tuberculosis was present in only three; and of a large number of cases which I have since observed, I am sure that the two affections have been associated in but a small proportion. As, however, there are grounds for believing that the occurrence of pleuritic effusion tends to retard, and contributes to the arrest of, the progress of tuberculosis, the association of the two affections may sometimes exist without being apparent.

Chronic, as well as acute, pleuritis occurs very rarely in infancy. It is not of infrequent occurrence in childhood and early life, but it is most frequent between puberty and middle life. It is of rare occurrence in the aged.

Prognosis.—Simple chronic pleuritis, not associated with tuberculosis, nor complicated with any serious affection, and occurring in a healthy subject, tends to recovery. A fatal result may take place in consequence of a rapid and large accumulation of liquid, but instances of this are exceedingly rare. If death occur, it is generally from associated affections or complications.

Recovery takes place, leaving the affected side more or less contracted; and sometimes the contraction is so marked as, in connection with the lateral curvature of the spine which it occasions, to produce an obvious and permanent deformity. In general, however, the contraction which follows is attended with little or no inconvenience, and is not observed unless the chest be denuded, and the two sides compared.

A permanent dislocation of the heart to the right side of the sternum is sometimes an effect of the removal of a large collection of liquid from the right pleural sac; and, in some cases of pleuritis, with large effusion in the left side, the heart, which was dislocated by the lateral pressure of the liquid, is found on the right side of the sternum after recovery from the pleuritis, adhesions having taken place which prevent it from returning to the left side after the liquid is removed.

Pulmonary tuberculosis becomes developed, sooner or later after recovery, in a certain proportion of cases. In some of the cases in which tuberculous disease appears to be a sequel, it may have existed prior to the pleuritis, and have undergone arrest. The proportion of cases in which tuberculous disease follows is not sufficiently large to show a predisposition to this disease derived from the pleuritis. The opinion, frequently and perhaps commonly entertained, that chronic pleuritis, when it does not supervene on a tuberculous deposit, predisposes strongly to the occurrence of the latter, I believe to be incorrect. This belief is based on my own experience. It is sustained by the statistics communicated by Dr. Blakiston.[1] Of fifty-three cases observed by this author, the patients remaining under observation for several years after recovery, not one became affected with pulmonary tuberculosis. This result is striking, for it might be expected that, out of so large a number of cases of any disease occurring, as does pleuritis, for the most part at an early age, a certain proportion would be likely, in the course of several years, to become tuberculous. In estimating the influence of this or any disease in determining the subsequent development of tuberculosis, the liability to the latter, irrespective of antecedent affections, is of course to be taken into account.

The idea has been suggested that, inasmuch as chronic pleuritis occurs oftener on the left than on the right side, its occurrence on the right side is evidence of its being connected with tubercle. This, however, appears to be disproved by the statistics reported by Dr. Bowditch.[2] Of fourteen patients affected with pleuritis seated in the right side, paracentesis being employed in all, 28.57 per cent. died, 64.28 per cent. were cured, and 7.14 per cent. remained doubtful. On the other hand, of eleven cases

[1] Practical Observations on Certain Diseases of the Chest, etc. American edition. Blanchard & Lea, 1848.

[2] *Vide* American Journal of the Medical Sciences. Number for January, 1863.

in which the left side was affected, paracentesis being employed in all, 45.45 per cent. died, 33.36 got well, and 18.18 were doubtful. These results disprove the idea just stated, because it is fair to conclude that the proportion of deaths would be greater, and of recoveries less, of those in whom the right side was affected, if a large number of this class of cases were tuberculous; whereas, these statistics show precisely the reverse.

The mortality from chronic pleuritis, even without regard to associated affections and complications, is not great. The rate of mortality in my own experience up to 1856, was 17 per cent.

Recovery is understood to imply the removal, by absorption, of the liquid effusion, and adhesion of the pleural surfaces. The affection, however, may terminate in another way, leaving no local symptoms, and the patient regaining good health. This consists in the affected side of the chest remaining permanently filled with liquid. The following case, illustrative of this termination, came under my observation in the Charity Hospital of New Orleans in 1861:—

A man, aged about 45, was admitted into a ward under the charge of my colleague, Dr. Fenner, stating that he had been ill and confined to the bed for four days, having previously been in good health. In answer to inquiries suggested by the marks of cupping on the left side, he stated that he had had pleurisy several years before. I saw the patient casually, and found the left side dilated, everywhere flat on percussion, and the respiratory murmur suppressed. Death occurred on the third day after his admission, and my notes do not contain data showing the probable cause of death. The man presented a robust appearance, and declared that he was quite well when seized with his present illness four days before his admission. His habits were intemperate.

On examination of the chest after death, the left pleural sac was found to be so resisting that it was removed entire, and brought to the college. The sac was then opened with some difficulty, and a large amount of turbid liquid, estimated to be two gallons, removed. After the liquid had escaped, the pleural sac was sufficiently rigid to retain the shape which it had before being opened. A chondroid formation, from one-eighth to one-quarter of an inch in thickness, lined the entire pleura. The parietal portion of the membrane could in some places be stripped from this chondroid formation. Calcareous matter was abundantly deposited in the latter. The lung was compressed into a solid, small mass, which resisted efforts at insufflation.

Another case, illustrative of a similar termination, so far as regards the permanency of liquid effusion, came under my observation in private practice. A lawyer, aged about 30, had an attack of pleuritis, which confined him for some time to the bed, nine years before my first examination in 1861. Five years afterward he was in excellent health, being entirely free from any pulmonary symptoms except deficiency of breath on exercise. Flatness on percussion existed over the whole of the left side, with suppression of the respiratory murmur and vocal resonance, except at the summit where bronchial respiration and bronchophony existed. These signs were considered as denoting liquid in sufficient quantity to fill the pleural sac and compress the lung into a solid mass. The patient stated that he had been repeatedly examined since the attack of pleuritis nine years before, and there had been no change in the condition of the chest since his apparent recovery from that disease.

Diagnosis.—Owing to the latency of chronic pleuritis, as regards the subjective symptoms, in many cases, the existence of intra-thoracic disease is often overlooked by those who do not employ physical exploration. Of

the cases which have come under my observation, in not a few the patients have been supposed to have dyspepsia, irregular intermittent fever, hepatic trouble, or some ailment not connected with the pulmonary organ. If the symptoms point to the existence of some affection within the chest, patients are often supposed to be tuberculous, and the cough, deficiency of breath, night perspirations, etc., rationally favor such a conclusion. A positive diagnosis can hardly be made without the aid of physical signs, but, with their aid, the existence of pleuritis is readily determined.

The signs on which, taken in connection with the history and symptoms, the diagnosis is to be based, are those denoting pleuritic effusion. The signs of liquid effusion are the same in chronic as in acute pleuritis, and need not be again stated; but in chronic, more frequently than in acute, pleuritis, the accumulation of liquid is so large as to occasion more or less dilatation of the affected side, and then are superadded signs obtained by inspection and palpation, notice of which was deferred in treating of the acute affection.

Dilatation of the affected side by liquid is apparent to the eye, and may be ascertained by mensuration, either with graduated tape or callipers. The intercostal spaces are pushed out to a level with the ribs, and may be bulging. The side is motionless, or nearly so, in the acts of respiration, the movements of the opposite side being exaggerated. By applying the fingers within the intercostal spaces and employing peripheral and diametrical percussion, a sense of fluctuation is sometimes obtained. The heart is moved from its normal situation, as ascertained either by palpation or auscultation. If the effusion be in the left side, the apex-beat or the maximum of the heart-sounds is on the right side of the sternum; and they are carried toward the left lateral portion of the chest if the effusion be in the right side. The diaphragm is depressed, pushing downward the abdominal organs in contact with it. The addition of these signs renders the diagnosis of pleuritic effusion still more complete and positive than the signs which denote the presence of liquid without dilatation.

During the stage of absorption, the signs show the progressive diminution of liquid until the quantity is no longer sufficient to occasion dilatation, and, from this point, the continued decrease in quantity is ascertained as in acute pleuritis. The contraction of the affected side which follows chronic pleuritis is more marked than that succeeding the acute affection.

Treatment.—The main objects of treatment in simple chronic pleuritis are twofold, viz: *First*, to aid in the removal of the effused liquid; and, *second*, to develop and sustain the powers of the system. For the first object, the measures which may be employed are the same as in the second and the third stage of acute pleuritis, consisting of the milder hydragogues, diuretics, small blisters applied in succession over different portions of the affected side, and the use of iodine internally and externally. In view of the anæmic state which generally exists, and the effect of mercurialization on the blood, this measure is contra-indicated. Bloodletting, general or local, is never indicated in chronic pleuritis.

In pursuing measures with reference to the first object, the second is not to be overlooked nor neglected. Cases are often injudiciously treated in consequence of the attention being too much engrossed with the measures to promote absorption; these measures will do harm if continued too long or pushed too far. After a certain amount of effect has been produced, if they cease to be further effective, they should be discontinued, at least for a time; nor should they be persisted in if they fail to have any effect.

Harm is produced by their injudicious employment, in proportion as they debilitate.

The second object calls for tonic remedies, nutritious alimentation, the moderate use of alcoholic stimulants, and gentle exercise out of doors. These measures are always important, and they are pre-eminently so if, from associated affections, complications, or the general condition of the patient, the powers of the system are notably lowered. I have repeatedly seen a marked change for the better occur at once, followed by progressive improvement in all respects, on the discontinuance of measures having reference to the absorption of liquid, and the substitution of measures addressed to the system. Hygienic measures, viz., nutritious diet and exercise in the open air, under proper restrictions, are especially important.

A mode of effecting the first object, viz., the removing of the liquid, requires distinct consideration. Reference is now had to the operation of *paracentesis* or *thoracentesis*. The propriety of puncturing the chest when the accumulation of liquid is sufficient to place the patient in imminent danger, is unquestionable. But it is a question which of late has been much discussed whether it be not advisable to puncture in cases in which the chest is dilated by liquid, although the patient be not in great distress or danger. It is clearly an object to get rid of the liquid, and the point to be decided is whether it be better to resort to the direct mode, that is, puncture and withdraw it, or to effect the object indirectly by purgatives, diuretics, etc. This point is to be decided, of course, after a consideration of the advantages and disadvantages of the operation of thoracentesis.

Heretofore, this operation was performed only as a *dernier resort*, under circumstances when little was to be expected from any measure. It was deferred as long as possible, sometimes on account of doubt as to the diagnosis, and because the perforation and introduction of air were supposed to involve danger of an increase of the inflammation. A considerable opening was necessary in order to give free exit to the liquid, and it was not easy to prevent the air from entering the pleural cavity. Objection to the operation on the score of diagnosis is now removed by our present knowledge of physical signs. Moreover, the operation has been divested of all severity, and the liability to the introduction of air has been provided against, by the application of the suction-pump, first suggested by Dr. Morill Wyman, in 1850, and since employed in a large number of cases by Dr. Bowditch. The introduction of air is not attended by the injurious effects formerly apprehended, but it is objectionable, because the presence of air is an obstacle to the full expansion of the lung after the liquid is removed. Its introduction is prevented by the use of the pump in withdrawing the liquid. The operation is rendered trivial because, with the suction force of the pump, a small exploring trocar suffices to make the puncture, which causes very little pain, and closes directly the canula is removed.

Dr. Bowditch operated in this way 250 times on 154 persons in the course of twenty years. In no instance was any permanent injury referable to the operation. It was in some cases repeated several times during the progress of the disease. In a considerable proportion of cases recovery appeared to be attributable to the operation. Immediate and great relief was obtained in cases which ultimately proved fatal. Dr. B. has been led by his experience to operate in all cases in which the quantity of liquid induces either permanent or occasional dyspnœa of a severe character, and in all cases in which the pleural cavity is filled, if, after a reasonable amount of treatment otherwise, the liquid does not diminish.

My own experience in the practice of the operation has been conside-

rable, and I can testify in behalf of its innocuousness, the relief which it affords, and its value as a means of rescuing patients from a condition of imminent danger to life. And the conclusions of Bowditch, as just stated, are not only sustained by his large experience, but are consonant with common sense. If by an operation trivial with respect to pain or any evil effects, and easily performed, the liquid effusion may be withdrawn at pleasure, this mode is certainly to be preferred to measures which are indirect, not very reliable, requiring considerable time, and producing more or less disturbance of the system and debility. An important advantage of the operation is, the liquid being removed before the lung has been subjected to long pressure, and has become adherent by dense layers of lymph, or, perhaps, organized tissue, the expansion takes place more fully, and is followed by less deformity of the chest from contraction of the affected side. It is a noteworthy fact that, directly after the operation, the temperature declines, and may fall to the normal standard.

Thoracentesis by means of a small trocar attached to the suction-pump, the puncture made at a convenient point either behind, laterally, or in front, is admissible whenever the pleural cavity remains filled with liquid after a brief trial of the measures designed to promote absorption; and the operation should not be delayed whenever the accumulation of liquid is sufficient to involve danger or distressing dyspnœa.

For several years past, in place of the suction-pump employed by Wyman and Bowditch, I have used a simpler apparatus, namely, a small trocar and canula fitted to screw upon the flexible suction-tube of Davidson's syringe. The canula should be provided with a stopcock. The trocar and canula being introduced into the chest, the trocar is withdrawn and the canula attached to the syringe; the liquid is then removed by means of the expansion of the India-rubber suction-bag after its compression with the hand. I have used this apparatus in many cases with satisfactory results. It has also been used with success by many others. In general, after a certain quantity of liquid has been withdrawn, the patient is seized with cough, and experiences a distressing sense of constriction in the chest. These symptoms probably arise from the atmospheric pressure upon the thoracic wall and from the disruption of the pleural surfaces, united by lymph, by the expansion of the compressed lung. They may also be, in part, due to the suction force exerted laterally upon the lung of the healthy side. They may be delayed, and sometimes avoided, by withdrawing the liquid very slowly, thus allowing time for the expansion of the compressed lung, and the gradual accommodation of the parts to fill the vacuum occasioned by the removal of the liquid. When these symptoms occur, the further removal of liquid had better be postponed for another operation. As regards the quantity removed at one operation, much will be gained by following the injunction to withdraw the liquid slowly, especially when the patient begins to cough and complain of constriction. The advantage of this apparatus over the suction-pump, is its greater simplicity, the ease with which it is managed, and a less liability to get out of order. A French instrument called the *aspirator* has these modifications: The cylinder is fixed upon a stand in an upright position, and is of glass; at the lower part there are two tubes, provided with stopcocks, one connected with a flexible tube attached to the canula, and the other connected with a tube through which the contents of the cylinder are discharged. By means of a piston, with a rack and pinion movement, the air is withdrawn from the cylinder, after which the stopcock attached to the tube connected with the canula inserted into the chest is turned, and the liquid flows from the pleural cavity into the cylinder. After the

cylinder is filled, its contents are expelled through the other tube, by turning the stopcock and allowing the piston to fall. This apparatus provides effectually against the introduction of air into the chest; but this is sufficiently provided for in the other instruments which have been described. The suction force operates steadily, and a very small trocar for penetrating the chest suffices. The cylinder being of glass, its contents are at once seen. The objections to the instrument are, first, that, being somewhat complicated, it is apt to get out of order; and, second, it is expensive as compared with Wyman's instrument, and especially with that devised by me. A little appendage has lately been added to the trocar to be attached to Davidson's syringe, so that it may be in an instant connected with the latter. It is easy to secure more expansive force than is obtained by the ordinary syringe used for enemata, by having an instrument made especially for thoracentesis, with a larger and thicker India-rubber suction-bag.

The conclusions drawn by Bowditch from the data afforded by his large experience, with respect to the character of the fluid withdrawn, and its influence on the prognosis, are of practical importance. A sanguinolent fluid, at the first puncture, denotes the existence of malignant disease of the lungs or pleura, and, consequently, the case will end fatally. A case presenting a mixture of bloody, purulent fluid at the first operation is usually fatal. A fetid, gangrenous fluid is very rare; it denotes gangrene, and the case will end fatally. In all such cases the operation may afford great relief and prolong life.

Empyema, Pyothorax, or Suppurative Pleuritis.

These names denote a variety of pleuritis characterized by the accumulation, in the pleural cavity, of a purulent liquid. The accumulation of pus is a feature sufficiently distinctive and important to serve as a ground for constituting this a variety of pleuritis. The term empyema only expresses the existence of pus, without indicating its situation. Pyothorax is a better name, but this does not express the existence of inflammation. Suppurative pleuritis is a simple title suggested as more fully expressive of the affection.

Suppurative pleuritis may be either acute or subacute at the beginning, but it becomes chronic. It is therefore a variety of chronic pleuritis. The symptoms attending its development are the same as in simple or ordinary pleuritis, either acute or chronic. There are no distinctive points pertaining to the symptomatology, and it is not necessary, therefore, to consider under a distinct head its clinical history. The anatomical characters, too, are essentially the same as in simple or ordinary pleuritis, excepting that, in the latter, the effused liquid is a mixture of serum and lymph, whereas, in the variety under consideration, the liquid contained in the cavity of the pleura is pus.

The pathological character of suppurative pleuritis is inflammation, acute or subacute, resulting in the accumulation of pus, or suppuration. This result of the inflammation is dependent on an intrinsic tendency existing at the outset. In other words, the accumulation of pus is not an accidental effect, nor does it depend on the duration of the inflammation. The inflammation in cases of suppurative pleuritis tends at once or speedily to suppuration. On the other hand, in cases of simple or ordinary pleuritis, the disease may continue for months and even years without eventuating in the accumulation of pus. The affection is not at first simple

and subsequently suppurative pleuritis, but it is a distinct variety of pleuritis from the beginning.

As regards its causation, it may be produced traumatically; and it occurs spontaneously, the internal causative agencies in the latter case being, with our existing knowledge, neither more nor less intelligible than when the inflammation is of the simple or ordinary kind. Why pleuritic inflammation in one case should lead to a collection of quarts or even gallons of pus, and, in another case, continue indefinitely without suppuration, we are unable to explain.

DIAGNOSIS.—The signs, as well as symptoms, in suppurative pleuritis are not distinctive of this variety. They represent the presence of more or less liquid in the pleural cavity, and they are essentially the same when the liquid is purulent as when it consists of serum and lymph. The point of inquiry, in regard of diagnosis, is, whether there be any means of determining that the liquid is purulent. This is an important point with reference to prognosis and treatment. The occurrence of chills, greater febrile movement, hectic paroxysms, etc., are not reliable in this differential diagnosis. As a rule, however, the axillary temperature is higher than in simple pleuritis. The symptoms and signs, in fact, exclusive of spontaneous perforation of the thoracic walls, will hardly warrant a positive diagnosis. But the purulent character of the liquid may be inferred with considerable confidence, if the quantity progressively continue to increase, notwithstanding the employment of measures to promote absorption. A serous effusion is generally either diminished or retarded by the use of hydragogues, diuretics, etc.; but these measures are not likely to exert any influence upon a purulent liquid.

Spontaneous perforation of the walls of the chest occurs, after a time, in cases of suppurative pleuritis. When this occurs, before ulceration of the integument ensues, a soft fluctuating tumor makes its appearance over or near the point of perforation. The appearance of such a tumor, developed rapidly without having been preceded by inflammation exterior to the thoracic walls, is at once significant of this variety of pleuritis. The size of the tumor may be observed to vary with forcible acts of inspiration and expiration. The action of the heart upon the liquid within the chest may communicate a pulsation to the tumor, and this may at first lead to a suspicion of aneurism; but an examination of the chest, by furnishing the evidence of the pleural sac being filled with liquid, will show the character of the affection. If the tumor be not opened, inflammation of the integument, from distension, and ulceration supervene, and the pus makes its escape from the tumor and the pleural cavity. "Paracentesis from necessity," as it is called, has then taken place. This result is almost exclusively due to suppurative pleuritis, but I have known an instance in which spontaneous perforation took place when the liquid was not purulent.

A positive diagnosis, however, may be made in cases in which spontaneous perforation of the chest does not occur, or without waiting for the occurrence of this event. A small exploring trocar may be introduced into the chest, and a few drops of the liquid withdrawn; the gross and microscopical characters of the specimen thus obtained will at once settle the question. This procedure is warrantable as a means of diagnosis in view of the bearing on the prognosis and treatment. Indeed, the operation is so slight as to be in no wise objectionable.

In a much smaller proportion of cases a spontaneous evacuation occurs in another direction. Perforation of the lung takes place, and the pus

finds its way into the air-passages. The occurrence of this event is marked by a sudden and copious purulent expectoration; this expectoration continues for an indefinite period. Perforation of both the walls of the chest and of the lung sometimes occurs.

Prognosis.—Suppurative inflammation of the pleura is a more serious affection than simple pleuritis, whether acute or chronic. Happily it is an unfrequent variety of pleuritis. Inasmuch as the pus cannot be removed by absorption, but must be evacuated either spontaneously or by surgical interference, the condition is analogous to that of a large abscess which, after opening, continues to discharge through a fistulous orifice. After the purulent contents of the pleural cavity are evacuated, the membrane continues to furnish pus, and thus the discharge continues indefinitely. Emaciation, debility, hectic paroxysms, etc., result from long-continued suppuration, and death takes place by slow asthenia. An unfavorable termination may be due, as in certain cases of simple pleuritis, to the coexistence of tuberculosis, pericarditis, or some other serious affection.

In the case of a patient ten years of age, which I saw with Dr. Dudley, of Brooklyn, sudden death followed perforation of the lung, the discharge of pus taking place rapidly, and causing suffocation by filling the bronchial tubes.

Recovery from suppurative pleuritis, however, is by no means unfrequent, and may reasonably be hoped for if the patient have a good constitution, and the affection be uncomplicated. The purulent discharge continues for weeks, months, and perhaps years, but progressively diminishes; pleuritic adhesions take place, the affection becoming more and more circumscribed, until, at length, they become universal, and the recovery is completed, leaving the affected side considerably or greatly contracted.

Treatment.—In the treatment of suppurative pleuritis, little or no reliance is to be placed on the employment of measures to promote absorption of the purulent liquid. If the pleural cavity be filled with pus, it will not be absorbed; but, if life be sufficiently prolonged, and thoracentesis be not resorted to, it will, sooner or later, make its way either into the air-passages or through the thoracic walls. Hydragogues, diuretics, blisters, etc., will not only prove unavailing, but they do harm, if persistingly employed, by impairing the powers of the system. Thoracentesis should be performed as soon as the purulent character of the liquid is ascertained, provided "paracentesis by necessity" have not already taken place. The suction-pump may be at first used, a larger trocar being advisable than when the liquid is serous, in consequence of the greater consistency of pus. The operation may be repeated as often as required, but, in the majority of cases, owing to the reproduction of pus, this mode of performing thoracentesis will prove unsatisfactory. An opening should then be made at the bottom of the pleural sac, allowing the pus to escape freely. Air will gain admission into the chest, and, since this is unavoidable, its ingress and egress should be unobstructed. A small orifice, not sufficient for the free escape of the pus, and allowing air to be pent up within the pleural cavity, is injudicious. The pus, becoming decomposed and fetid, acts as an irritant on the inflamed surfaces, whereas if it drain away as fast as it is formed, and the cavity of the pleura be well ventilated, this result does not follow.

If spontaneous perforation take place, as denoted by the development of a fluctuating tumor, the latter should be at once opened. If the per-

foration be at a point so far above the bottom of the sac that a portion only of the pus is evacuated, more or less remaining constantly below the point of perforation, a counter-opening should be made. It is desirable that the drainage should be so effectual that there will be little or no fetor connected with the discharge. If there be fetor, injections of tepid water are useful. I have known these to be extremely useful in effecting the removal of fetid pus, when the perforation was not at a favorable point for the free discharge of the purulent contents of the pleural sac.

To support the powers of the system is an object of still greater importance in the treatment of suppurative, than of simple, pleuritis. The importance is greater because there is more danger of death by asthenia, and, in favorable cases, the duration of the affection is longer. The measures to be employed for this object are the same in both forms of the disease.

Pleuritis with Pneumothorax, or Pneumo-hydrothorax.

The term pneumo-hydrothorax denotes the presence of air or gas and liquid in the pleural cavity. As the liquid, however, is either sero-fibrinous or purulent, hydrothorax, which signifies a purely serous liquid, is not strictly appropriate; the liquid is due to inflammation, and the affection is a variety of pleuritis. It would be more correct to say, pleuritis with pneumothorax. Pneumothorax denotes the presence of air without liquid; the latter affection is rare, but it occurs, and claims separate notice.

Pneumothorax coexists with suppurative pleuritis, after a spontaneous perforation of the thoracic walls, or when a fistulous opening is made; and also in the rare cases in which the lung is perforated from the pleural surface, and a communication thus opened between the air-passages and the pleural cavity. But the term pneumothorax, with or without pleuritis, is considered as denoting the presence of air in the cavity of the pleura, the air generally gaining admission from the air-passages through a perforation which, in most cases, takes place from within the lung. This perforation, in the vast majority of cases, is an accident occurring in the progress of pulmonary tuberculosis. It is possible that gas may be generated by the decomposition of pus in some cases of suppurative pleuritis, and that the affection under consideration may be thus produced without perforation either of the lung or the parietes. Instances, however, of this kind, if they ever occur, must be extremely rare.

It is probable that perforation of the lung would occur much oftener than it does, were it not for the constancy with which circumscribed, dry pleuritis, leading to pleuritic adhesions, supervenes upon tubercle. Over the portions of lung in which the tuberculous affection is seated, the pleural surfaces usually become firmly united, requiring often considerable force for their separation on post-mortem examinations. These adhesions offer an obstacle to the evacuation of collections of liquefied tubercle into the pleural cavity, and the evacuation is usually into the bronchial tubes. But, occasionally, a collection of liquefied tubercle being situated near the superficies of the lung, at a point not protected by adhesions, the membrane gives way and the evacuation is into the pleural cavity. Pleuritis, under these circumstances, is at once excited, air finds its way through the perforation, and in this way the pneumothorax becomes developed. The perforation is rarely at the summit, but is situated at the middle or inferior portion of the lung.

In like manner pleuritis with pneumothorax is produced in certain cases of circumscribed, pulmonary gangrene. The decomposed pulmonary tissues are usually evacuated into the bronchial tubes and expecto-

rated; but sometimes, being situated near the surface, the pleura at that point becomes involved in the gangrene, and gives way, leaving a perforation through which air enters the pleural cavity, and pleuritis is caused by the presence of the sphacelated matter. A few instances of this kind have come under my observation.

Anatomical Characters.—Gas escapes with more or less force after the knife penetrates the chest, in making the post-mortem examination. The gas consists of carbonic acid and nitrogen. The pleural sac contains liquid in variable quantity in different cases. The liquid is turbid from admixture with lymph. The pleural surfaces are more or less covered with lymph, which is soft or dense, according to the duration of the affection. The air and liquid are sometimes extremely fetid, and in other cases devoid of fetor. The fetor is excessive if the affection be associated with pulmonary gangrene. After the sternum is removed, if the nozzle of a pair of bellows be inserted into the trachea, and air forced into the lung of the affected side, bubbles rising in the liquid show the fact of perforation and its situation. The size of the perforation varies. It is usually small when the affection supervenes on tuberculosis; but it may be quite large in cases of gangrene. The lung on the affected side, if not prevented by old adhesions, is compressed into a solid mass, as in cases of simple pleuritis with large effusion.

Clinical History.—The occurrence of perforation is usually marked by acute pain denoting the development of pleuritis. The introduction of air, and the speedy effusion of liquid, give rise generally to notable dyspnœa, with accelerated breathing, accompanied frequently with lividity. The pulse is in most cases rapid and feeble. These symptoms show the supervention of a serious affection of some kind, and point to the chest as its seat.

In some cases the accelerated breathing and dyspnœa continue to be prominent symptoms, the patient suffering greatly, and perhaps being unable to lie down (orthopnœa), until the affection ends fatally, which, under these circumstances, is usually after the lapse of a few days, and it may end fatally in the course of a few hours. But, in other cases, the violence of the symptoms subsides after a short time, and the dyspnœa may be moderate, or wanting, save on exercise. In some instances, even considerable exercise is practicable. As regards strength and the general condition, there is much variation in different cases. In the majority of cases, patients are confined to the room and bed, but sometimes they are able to be out of doors, preserving appetite, and not presenting a notably morbid aspect. Much will, of course, depend on the condition as regards the affections of which this is a complication.

As an exception to the rule, pleuritis, with pneumothorax from perforation, is developed gradually and imperceptibly. It may remain for a greater or less period quite latent. In some instances the accumulation of liquid becomes large, the air disappears, and the affection is apparently converted into simple pleuritis with effusion. In several instances of this kind which have fallen under my observation, thoracentesis was resorted to, and the communication between the air-passages and pleural cavity, through the perforation, was resumed after the liquid was withdrawn.

Diagnosis.—When this affection is developed with marked symptoms in the course of pulmonary tuberculosis, its existence should certainly be at once suspected; but the symptoms are not sufficiently distinctive of

this affection, as contrasted with simple pleuritis and effusion, to warrant a positive differential diagnosis. Moreover, as just stated, the affection is sometimes latent, the symptoms not warranting even the diagnosis of pleuritis. A positive diagnosis, in short, must be based on physical signs, and these are usually easily obtained and very explicit.

The presence of air in the pleural cavity renders the percussion-sound purely tympanitic. If the quantity of liquid be small or moderate, tympanitic resonance may extend over the whole of the affected side, being propagated from the level to the bottom of the liquid. If the liquid be large or considerable in quantity, dulness or flatness will be found at the base and extending upward (the patient sitting) to a certain height, tympanitic resonance existing above. Under these circumstances, the relation of resonance and dulness or flatness will be found to vary with the changed position of the body of the patient. The tympanitic resonance sometimes has an amphoric character.

Respiratory sound is sometimes wanting over the whole of the affected side. Over the compressed lung bronchial respiration may be found. The ordinary cavernous respiration is sometimes heard, but, in most cases, amphoric respiration and amphoric voice or echo are present, either limited or diffused over the whole of the affected side, and metallic tinkling is generally conjoined. The presence of these striking and distinctive signs renders the diagnosis easy and positive, taken in connection with other signs.

Succussion in most cases develops a splashing sound, frequently having the same kind of musical intonation as the respiration, voice and tinkling sounds. This proof of the presence of air and liquid is positive and rarely wanting.

The affected side is frequently dilated, and presents the same characters as in cases of dilatation from liquid in simple and suppurative pleuritis.

Prognosis.—The prognosis, in cases of pleuritis with pneumothorax, is always unfavorable. In this statement traumatic cases are excluded; the prognosis in these cases is generally favorable. If the affection be connected with pulmonary gangrene, death takes place invariably and within a short period. Other things being equal, when it occurs in the course of pulmonary tuberculosis, a fatal termination is speedy in proportion to the progress which the latter affection has made. There is a wide variation in different cases as regards its duration before a fatal ending; in most cases it ends fatally within a few days or weeks, but sometimes life is prolonged for months or even years. It may continue for an indefinite period, the patient experiencing so little inconvenience as to consider himself in good health. The following remarkable case will serve to verify this statement, and also illustrate the latency of the affection occurring in connection with tuberculosis:—

I received from Dr. J. H. H. Burge, of Brooklyn, N. Y., the left lung which he had removed at a post-mortem examination made two or three days before. The patient, aged eighteen, an accountant, was seized, four days before his death, with an acute affection which proved to be pneumonitis affecting the lower lobe of the right lung. At the time of the attack he considered himself in good health. He was attended by Dr. Burge, who found the physical signs denoting pneumonitis, and the affected lobe was found after death in the second stage of this disease. On an examination of the chest, in addition to the pneumonitis, Dr. Burge discovered the signs of pneumo-hydrothorax affecting the left side. Metallic tinkling, and amphoric respiration and voice, were finely marked. The upper por-

tion of the chest on this side yielded a tympanitic, and the lower portion a dull resonance on percussion.

On inquiry as to the previous health, the patient stated that he was quite well when attacked with the acute disease; that is, four days before his death. On close questioning, however, it was ascertained that he had had a slight cough for a year, but so slight that he thought nothing of it. He was not conscious of any deficiency of breath, was not subject to pain in the side, and, in short, there were no symptoms pointing to so grave an affection as pleuritis with pneumothorax.

The left lung was completely condensed from compression. The lower lobe was readily inflated; the upper lobe but slightly, owing to the free escape of air through a perforation as large as a crow's quill, situated on the anterior aspect of this lobe, about midway from the upper to the lower extremity. On closing the aperture, this lobe was readily inflated. The perforation was gaping, the orifice being surrounded by a cartilaginous rim. On passing a probe into the aperture, it entered a small cavity of about the size of an American walnut. The cavity was smooth and lined by a membrane. This was the only cavity in the left lung, and there were no tuberculous masses. The whole surface of the lung was covered with lymph dense and closely adherent. The pleural cavity contained over a quart of turbid liquid, which was not fetid. When this side of the chest was opened, air escaped with force, emitting no fetor. The upper portion of the right lung contained several tuberculous cavities, the largest of the size of an English walnut; also, small masses of crude tubercle.

I exhibited the perforated lung at a meeting of the New York Pathological Society, March 27, 1862.

Treatment.—The treatment of pleuritis with pneumothorax, in most cases, embraces only palliative and sustaining measures. The severity of the pain and the distressing dyspnœa frequently call urgently for measures to procure relief. Opium, soothing applications to the chest, and the ethereal preparations are indicated for this object. The powers of the system are to be sustained by tonic remedies, alcoholic stimulants, and a nutritious diet. These measures will generally only serve to mitigate the sufferings of the patient and prolong life; and in the rare cases in which the affection continues for months, or years, or indefinitely, and is not incompatible with comfortable health, there is no special treatment to be pursued, the main object being to invigorate and support the powers of the system.

If the patient suffer greatly from dyspnœa arising from dilatation of the affected side, the chest may be punctured as a palliative measure. I have resorted to this operation to the great relief of the patient. The air will be likely to reaccumulate, and the side become again dilated as before; but I have known this not to occur for some weeks, and the operation may be repeated as often as called for by the dyspnœa arising from the dilatation.

Pneumothorax.

The term pneumothorax denotes the presence of air, without liquid, in the pleural cavity. Under these circumstances, pleuritis either does not exist, or it is circumscribed and not accompanied by liquid effusion. This affection is certainly extremely rare; its occurrence has been doubted, but its existence is sufficiently established. In cases of pneumothorax, without pleuritis, the perforation of lung is not incident to gangrene or tuber-

culosis, but is probably connected generally, if not invariably, with emphysema, which may not be general, but circumscribed. Emphysematous dilatation of the air-cells, perhaps confined to a few lobules at the margin of a lobe, or an emphysematous bleb, may lead to a minute rupture through which air is forced, by the acts of breathing, into the cavity of the pleura. The perforation, as remarked by Dr. Gairdner, may be no larger than a pin-hole. The presence of the air does not excite pleuritis, but the accumulation may be sufficient to compress the lung into a solid mass, as in pleuritis with large effusion, dilating the affected side, and removing the heart from its normal situation.

Pneumothorax, without effusion from pleuritis, is characterized by the absence of the symptoms and signs denoting inflammation and the presence of liquid. The patient suffers chiefly from the mechanical effects of the presence of air. These effects relate exclusively to the respiration and circulation. There is little or no febrile movement; the appetite, digestion, and nutrition are not affected, and the vital powers are maintained. If the affection were to end fatally, it would be by apnœa, assuming that pleuritis is not developed sooner or later. It is unquestionable that this affection may end in recovery. Under the influence of compression, the perforation may become sealed up by a circumscribed pleuritis with the exudation of lymph, or subsequently by the adhesion of the pleural surfaces at the point of perforation, and the lung again become expanded and resume its function. Dr. Gairdner has quoted the report of a remarkable case illustrative of the occurrence of pneumothorax without pleuritis, and of its favorable course and termination.[1] Dr. Gairdner regards this case as unique in respect of the distinctness of the clinical facts on which the diagnosis was based. A case equally striking, and not less distinct as regards the diagnostic phenomena, has fallen under my observation. The important points taken from the history of this case, which was recorded very fully, are as follows:—

A Polish peddler, aged 29, was admitted into hospital, January, 29, 1856. He stated that twelve days before his admission, being apparently in perfect health, he was attacked suddenly with a sharp pain in the region of the left nipple, accompanied with shortness of breath. This occurred while he was carrying his pack, which weighed about 70 pounds. He had no cough nor expectoration. The pain soon disappeared, but the want of breath obliged him to give up his occupation and led him to the hospital. He was a vigorous man, weighing about 175 pounds. He presented a healthy aspect, complaining only of deficiency of breath on exercise. This difficulty did not prevent him from being up and walking freely about the ward.

The left side was dilated, and the intercostal depressions obliterated; the resonance over this side was purely tympanitic, and auscultation furnished a well-marked amphoric echo without any respiratory sound. Subsequently amphoric respiration became extremely well marked, together with metallic tinkling. The heart-sounds showed the heart to be to the right of the sternum.

After a month there was considerable improvement as regards the deficiency of breath on exercise. The dilatation of the left side was no longer apparent, and the intercostal depressions became visible; vesicular respiration extended from the summit to the nipple, and the amphoric sounds, with the metallic tinkling, had disappeared.

Three weeks afterward, the patient felt sufficiently improved to leave

[1] Clinical Medicine. Edinburgh, 1862, page 381.

the hospital and return to his occupation. The respiratory murmur on the left side was feeble, but everywhere appreciable, with no abnormal modification, save in intensity, and no amphoric sounds. The impulse of the heart was felt on the left side of the sternum.

The patient consulted me a month after his discharge from the hospital. He had returned to his occupation of peddling, carrying his pack on his back as before. He had experienced no difficulty from want of breath until three days before his visit to me; but for three days the deficiency of breath on exercise had been considerable. On examination of the chest, the left side was everywhere tympanitic; there was no respiratory murmur on that side, and the heart was on the right side of the sternum. No amphoric sounds. He complained of nothing but the want of breath; excepting this, he was well.

I did not see the patient afterward for eleven months. At the end of that time he called to see me with another patient. After his former call upon me, he gave up peddling and became a farm-laborer. He now appeared and reported himself to be perfectly well. The respiratory murmur was everywhere heard over the left side, but was slightly weaker than on the right side. The apex-beat of the heart was in its normal situation. The left side latterly and posteriorly presented to the eye slight contraction.

This was evidently a case of simple pneumothorax, without pleuritis. A pin-hole perforation at a weak point, or the rupture of an emphysematous bleb, probably took place under the muscular exertion of carrying his pack. He had nearly recovered when, on resuming his occupation, the perforation was reopened, and the pneumothorax reproduced. Recovery again took place, and after the lapse of several months, appeared to be permanent.

A sufficient number of cases of pneumothorax, without pleuritis, to serve as a basis for the clinical history and prognosis, are not yet available. The infrequency of the affection is such, that the collection of a considerable number of cases for analysis cannot soon be expected. The case just given, and the case recently reported by Gairdner, go to show that a favorable prognosis may be entertained.

As regards treatment, it is obvious that no special course of medication is called for. The compression of lung probably favors the healing up of the perforation, so that it would not be advisable to puncture the chest in order to allow the air to escape. Active exercise or muscular efforts, as in straining, are to be avoided, not only during the continuance of the affection, but for some time after recovery, lest the orifice may be reopened, as in the case just detailed. Soothing embrocations to the chest will be useful as palliatives; but nothing can be gained by active counter-irritation. A nutritious diet may be allowed. Cathartics, diuretics, and rubefacients are not indicated.

Circumscribed Pleuritis.

The frequency with which pleuritic adhesions, over a limited area, are found after death, is proof that circumscribed pleuritis often occurs. But the inflammation which results in these adhesions is often subacute, and generally occurs without giving rise to much pain or other disturbance. As already stated, circumscribed pleuritis is secondary to some pulmonary affection, especially tuberculous disease and pneumonitis, and it differs from a primary general pleuritis in not giving rise to pleuritic effusion. Fibrinous exudation is sometimes small, and, perhaps, may be altogether

absent, the adhesions taking place purely by a hyperplasia or proliferation of the connective tissue. Limited to the pleura investing the diaphragm (diaphragmatic or phrenic pleuritis), inflammation is supposed to give rise to symptoms which are distinctive, viz., hiccough, attended with pain, and pain referable to the diaphragm in the acts of coughing. It may be doubted, however, if these symptoms are sufficient to mark the situation of inflammation, or to distinguish inflammation from pleurodynia. If, from the symptoms, circumscribed pleuritis be suspected, the treatment indicated embraces moderate counter-irritation, soothing applications to the chest, and anodyne remedies. It may fairly be doubted whether acute, primary pleuritis be ever circumscribed. The successive attacks of circumscribed pleuritis which occur during the progress of pulmonary tuberculosis, and which lead to firm adhesions, are seldom accompanied by much pain, and only call for palliative measures.

Circumscribed collections of sero-fibrinous or purulent liquid are usually, if not always, preceded by general pleuritis which has led to the adhesions surrounding the space in which the liquid is contained. These collections may be situated at the lower part of the chest, between the lung and diaphragm, or between the lobes. The previous history and the appearances of the chest will generally show the prior existence of general pleuritis. The diagnosis of circumscribed collections of liquid is not always easy. For the physical signs, the reader is referred to works which treat more fully of thoracic diseases. The treatment embraces the measures for promoting absorption; and, if there be grounds to suppose that the liquid is purulent, after this fact is demonstrated by means of the exploring trocar, it may be advisable to effect the removal of the liquid by paracentesis.

Hydrothorax.

Hydrothorax, using the term correctly, is not a variety of pleuritis, but it is noticed in this connection because, so far as certain symptoms and physical signs are concerned, it has points in common with pleuritis accompanied by liquid effusion. In the proper sense of the term, it denotes a dropsical affection. The effused liquid is serum devoid of lymph. The effusion is not a result of inflammation or any other affection of the pleural membrane, but proceeds from the conditions, relating to the blood and circulation, on which dropsical effusion in other situations depends. It very rarely occurs alone, but is generally an element of general dropsy; that is, dropsical effusion exists at the same time in the peritoneal cavity and in the subcutaneous areolar tissue, the latter constituting either œdema or anasarca. As a rule, in cases of general dropsy, the hydrothorax is subsequent to the anasarca and to hydroperitoneum.

The signs which denote the presence of liquid in the pleural cavity are alike applicable to inflammatory and dropsical effusion. The proof afforded by the change of level of the liquid, corresponding with changes of the position of the body, is more constantly available in hydrothorax, because lymph is not present to agglutinate the pleural surfaces and lead to permanent adhesions. But the distinctive feature of this affection is the existence of effusion in both pleural cavities. Hydrothorax is bilateral, provided the pleural cavity on one side be not abolished by universal adhesions due to a previous attack of pleuritis, whereas, pleuritis, when it is primary, is unilateral. The amount of dropsical effusion, however, in both sides, is generally not uniform. It is not uncommon to find in the pleural cavity on one side a quantity of liquid considerably larger than is contained in the cavity on the other side. It may then be laid down as a

rule, that, if the physical signs show the presence of liquid in both sides, and general dropsy coexist, the affection is hydrothorax. A friction murmur is, of course, not developed in this affection.

Symptoms denoting inflammation, viz., pain, cough, febrile movement, do not belong to the clinical history of hydrothorax. The respirations are increased in frequency, and the patient suffers from deficiency of breath, or dyspnœa, in proportion to the amount of dropsical effusion. Existing in both sides, it is obvious that the embarrassment of respiration will be the same as if all the liquid were in one pleural cavity, and twice as much as if the effusion in one side were unaccompanied by an equal effusion in the other side. If there be considerable effusion, dyspnœa will be marked, amounting perhaps to orthopnœa, and death by apnœa may be due to the amount of effusion. Cardiac lesions, producing obstruction of the mitral orifice, especially favor the occurrence of hydrothorax, after these lesions have led to dilatation of the right cavities of the heart.

The measures of treatment in hydrothorax are those indicated in general dropsy, and these need not be considered in this connection. It is rarely the case that the affection occurs under circumstances calling for paracentesis. This operation, however, is admissible, as a palliative measure, if the amount of effusion be sufficiently large to occasion great suffering or endanger life. I have resorted to it in a case in which the danger of death by apnœa was imminent, great temporary relief being obtained by it, and the life of the patient being apparently prolonged. As there is no obstacle to the expansion of the compressed lung in cases of hydrothorax, all the effused liquid may be at once removed without the distress which is apt to accompany the operation of thoracentesis in cases of pleurisy.

It should be added that in some cases in which it is dependent on mitral obstruction, hydrothorax is greatly out of proportion to the amount of dropsical effusion in other situations; and I have repeatedly observed prompt, complete, and permanent relief procured by the hydragogue operation of elaterium in these cases.

CHAPTER IV.

PNEUMONITIS.

Seat of the Inflammation. Varieties. Acute Lobular Pneumonitis—Anatomical Characters—Laws of the Disease—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis.

HAVING considered in the preceding chapters inflammation affecting the serous membrane investing the lungs, inflammation seated in the pulmonary substance or parenchyma is next to be considered. The latter is called *pneumonitis*, or *pneumonia*. Pneumonia is the name commonly used; pneumonitis, however, is the name used in this work in comformity with the plan of distinguishing inflammatory affections by the suffix *itis*. The question at once arises, what constitutes the parenchyma, or substance of the lungs. These terms relate to the air-cells, vesicles, or alveoli,

together with the bronchioles or terminal bronchial branches. They are lined by a membrane differing materially from the mucous membrane lining the successive divisions of the bronchial tubes. The membrane which lines the air-cells and bronchioles is distinguished by its tenuity, by the absence of mucous follicles, and by a change of epithelium from the cylindrical and ciliated to the squamous, pavement, or tessellated variety. The air-cells and bronchioles make up the lobules, and these, united by means of areolar tissue, constitute the lobes into which each of the two lungs is divided. In acute pneumonitis, the membrane lining the air-cells and bronchioles is inflamed. The differences in the structure of this membrane, as compared with the bronchial mucous membrane, together with a difference of function, will serve to account for the fact that the inflammation in pneumonitis may be limited to the pulmonary substance, and, also, the fact that in bronchitis the inflammation rarely extends to the pulmonary parenchyma. This is in accordance with a pathological law, viz., that inflammation of a structure does not, as a rule, extend to another structure, however proximate, which has important anatomical differences, or which differs as regards its functions. Some striking examples of conservatism in disease will be found to hinge upon this pathological law. The fact, also, that the lining membrane of the air-cells is not, strictly speaking, a mucous membrane (since it is devoid of mucous follicles) will account for important differences pertaining to the inflammatory products of pneumonitis when compared with bronchitis and other mucous inflammations. The relation of the air-cells to the terminal branches of the pulmonary artery is also involved in the pathological phenomena of inflammation of the parenchyma of the lungs.

Acute pneumonitis, when it is not a complication of an existing pulmonary disease, usually affects, at least, an entire lobe; and this extension of inflammation is expressed by the term *lobar pneumonitis*. Developed in the course of another pulmonary disease, it may be more or less limited. When limited to a portion of a lobe, it may be distinguished as *circumscribed pneumonitis*.

A distinct section will be devoted to chronic pneumonitis; and under this head will be noticed induration, sclerosis of the lung, together with anthracosis, siderosis, and pigment or brown induration. The terms lobular and disseminated pneumonitis have been used to denote an affection of isolated lobules, more or less in number, in both lungs. This will form the heading of a separate section, which will embrace some account of atelectasis and collapse of pulmonary lobules. Acute lobar pneumonitis will be first considered. By German writers, this affection is called croupous pneumonitis; and, by some French writers, fibrinous pneumonitis.

Acute Lobar Pneumonitis.

Anatomical Characters.—The first appreciable change resulting from acute inflammation is the same here as in other situations, viz., an abnormal accumulation of blood, or hyperæmia, due to active congestion or engorgement. The inflamed portion of the lung is heavier than in its healthy state; on section, the cut surfaces present a dark appearance, and blood flows in abundance, together with serous liquid more or less frothy. It would not be easy to discriminate between hyperæmia arising from inflammation and that due to hypostatic congestion, by the appearances. But the latter affects the portions which are dependent and is not limited to one lung, whereas the former is confined to one side and not always

limited to the position into which the blood would accumulate by gravitation. The hyperæmia does not prevent air from entering the air-cells. Into the latter, however, soon, or from the first, is effused a little albuminous liquid. This condition lasts but for a short period.

Exudation speedily follows. A coagulating material escapes from the blood, and coagulates within the air-cells. The cells are filled and distended with the exuded matter. They cease to contain air. The lung is solidified, presenting an appearance not unlike that of the liver, and hence this condition has been called *hepatization*. In this condition usually the lung contains but little blood, and presents a pale, anæmic aspect; hence the term red hepatization is inaccurate. The red coloration, when present, denotes an unusual proportion of the red globules in the exudation within the cells. Closely examined, the cut surfaces have a granular appearance. When the hepatized part is divided, more or less liquid escapes and contains no air bubbles. The substance of the lung is softened, breaking down under the pressure of the finger more readily than in its healthy state; that is, it is more friable. Its weight is much increased; a single lobe solidified by inflammatory exudation increases in weight from one to two pounds, and an entire lung solidified may acquire an additional weight of four pounds. This increase in weight is due, not to an accumulation of blood, which is less than in health, but to the amount of solid matter withdrawn from the blood. Owing to the absence of air, portions of the solidified lung sink when thrown into water. The volume of the affected lobe or lobes is large in proportion to the amount of exudation, and no collapse occurs when the chest is opened. Examined with the microscope, the substance blocking up the air-cells is found to be composed of molecular matter which is probably amorphous fibrin or lymph in a granular form, epithelium, fatty granules, blood disks, and leucocytes.

If the progress of the disease be favorable, the exudation is removed mainly or exclusively by absorption. It may be absorbed with great rapidity. The statement by Rindfleisch, and others, that the greater part of the exudation is expectorated, is certainly incorrect. The matter expectorated, in general, bears no proportion to the quantity of exudation; and cases are not rare in which the exudation disappears without any expectoration. After its removal, the air-cells are found to have sustained no damage. The pulmonary structure remains intact while the exudation remains, and its functional capacity is fully restored after the exudation disappears. The circulation, too, is again restored as in health, and the recovery of the affected part is complete.

If the progress of the disease be unfavorable, absorption of the morbid products within the air-cells does not take place, and the affected lobe or lobes are infiltrated with liquefied fibrin and pus. This condition is called purulent infiltration. The lung presents a grayish appearance. When divided, a purulent liquid flows freely from the cut surfaces. The substance is much softened, breaking down on slight pressure. Occasionally, collections of pus take place forming pulmonary abscesses. Gangrene of the affected portion of lungs sometimes occurs, but this, as well as the occurrence of abscess, is extremely rare.

Pleuritis, limited to the affected lobe or lobes, usually occurs and is developed coincidently with the pneumonitis. In a small proportion of cases the concurrent pleuritis is wanting. It varies much in degree in different cases, being sometimes slight and sometimes severe. The exudation of lymph on the pleuritic surface over the affected lobe or lobes, varies in amount. Much liquid effusion into the pleural cavity occurs only as an exception to the rule; the pleuritis, in most cases, is circum-

scribed and dry. The terms *peripneumonia* and *pleuropneumonia* denote the coexistence of pleuritis and pneumonitis. Inasmuch as pleuritis is very rarely wanting, these terms are applicable to nearly all cases of pneumonitis. They may, however, be applied to distinguish cases in which the pleuritis is unusually prominent and attended with more or less liquid effusion. It is quite unnecessary to consider these terms as denoting a distinct variety of pneumonitis.

More or less bronchitis, affecting the bronchial tubes within the affected lobe or lobes, usually exists with pneumonitis. In some cases, however, the pneumonitis passes through its whole course without affording any evidence of this limited bronchitis. Bronchitis affecting the bronchial tubes of both lungs is sometimes, but rarely, present with pneumonitis. When these two affections are combined, it is accidental; bronchitis, as the primary affection, does not tend to the development of pneumonitis, and the latter has no tendency to give rise to bronchitis save within the affected lobe or lobes.

To the foregoing sketch of the anatomical characters may be added certain laws of the disease, which are best presented in this connection. One of these relates to the situation of the disease. Pneumonitis attacks, in the great majority of cases, the lower lobe, and the lower lobe of the right, oftener than of the left, lung. Exceptionally, it sometimes attacks primarily an upper lobe, and in these cases, as a rule, the disease is more severe; but to this rule there are exceptions. The disease very rarely, if ever, attacks two lobes simultaneously, but it invades, not infrequently, in succession a second and even a third lobe. The inflammation does not extend from one lobe to another, but, whenever a new lobe is affected, it is the seat of a new invasion. The lobes of one lung may be successively invaded, or a single lobe on both sides; or, an entire lung being first affected, a lobe of the other lung may be attacked. In the two latter cases the pneumonitis is said to be double.

The inflammation extends at least over an entire lobe, as the name lobar pneumonitis implies, in the great majority of cases. There are exceptions to this rule. I have known some instances in which the physical signs clearly showed the occurrence of inflammation extending over a limited area, without any evidence of the circumscribed pneumonitis being a complication of any other pulmonary disease. In a lobe invaded secondarily, that is, one lobe being already affected, the inflammation is sometimes found after death to have extended over a portion only of the lobe. This fact I have repeatedly noted, but, perhaps, had the life of the patients been prolonged, the whole of the lobe would have been affected.

The whole of the lobe first invaded is not at once affected. The inflammation begins at a certain point, or at several distinct points, and extends from lobules to lobules until the entire lobe is involved. The point or points of departure may be at either the upper or lower extremity of the lobe, and at either the superficies or centre of the lobe. The diffusion of the inflammation over the lobe takes place with more or less rapidity; sometimes a few hours suffice, but in some cases it occupies several days. The progress of the solidification from the exudation may be determined very accurately from day to day, or from hour to hour, by means of physical signs.

The inflammation very rarely ends with the occurrence of engorgement only, without exudation. Solidification almost always occurs, and, when the inflammation is not secondary to another pulmonary disease, usually extends over to the lobe or lobes invaded.

With respect to the situation and extent of the affection, the following

are the results of an analysis of 121 cases:[1] In 29 cases it was limited to the lower lobe of the *right*, and in 25 cases to the lower lobe of the *left* lung. It extended over the whole of the *right* lung in 27, and over the whole of the *left* lung in 9 cases. It was limited to the upper lobe of the *right* lung in 8, and to the upper lobe of the *left* lung in 3 cases. It was seated in the lower lobe of both lungs in 8 cases.

Clinical History.—The division of the career of acute pneumonitis into stages is based upon differences as regards the anatomical characters at different periods of the disease. The *first* stage embraces the period during which the affected lobe is in the state of active congestion or engorgement. This stage is called the stage of engorgement. The disease is considered as passing into the *second* stage when the affected lobe, or a greater part of it, has become solidified by the inflammatory exudation. This stage is called the stage of solidification or hepatization. In the *third* stage the affected lobe is in one of two conditions. If the disease pursue a favorable course, the third stage begins when it is evident that absorption of the exuded matter is going on, and convalescence takes place during this period. This may be called the stage of resolution. If the disease pursue an unfavorable course, the third stage is one of suppuration or purulent infiltration, and this stage may be called the purulent or suppurative stage. If this stage occur, the disease generally ends fatally.

The duration of each of these stages varies much in different cases. The stage of engorgement may last but for a few hours. I have known an entire lobe to be solidified by two pounds of exudation matter, as determined after death, in less than twelve hours. Not infrequently this stage does not extend beyond twenty-four hours. But sometimes the solidification occupies two, three, or four days, and in some cases it occupies even a longer period. In the majority of cases this stage is from twenty-four to forty-eight hours in duration. The stage of solidification may also be of short duration. I have known resolution to commence and make considerable progress in twenty hours. But its commencement may not be evident for two, three, or four days, or even for a considerably longer period. In the majority of cases the duration of this stage is from two to four days. The stage of resolution is still more variable. There is a notable difference in different cases as regards the rapidity or slowness with which the solidifying deposit is removed. It is very rarely the case that the resolution is completed in less than three or four days, and generally eight or ten days are required. In some cases two or three weeks elapse before the air-cells are restored to their normal condition, and occasionally the resolving process is even more protracted. If the disease pass into the purulent stage, death usually takes place within a few days; but if the disease ends in recovery, many days and perhaps weeks elapse before the normal condition is restored.

In the great majority of cases, acute pneumonitis commences with a well-pronounced chill, frequently accompanied by rigors. The thermometer in the axilla at this period of the disease shows an increase of the temperature of the body, although coldness exists as a subjective symptom. The invasion is usually abrupt, with few or no premonitions. The attack is apt to occur during the night. Coincident with, or speedily following the chill, is the occurrence of pain. The pain is frequently severe. It is acute, lancinating, and in all respects identical with the pain

[1] Clinical Report on Pneumonia, based on an Analysis of 133 Cases. By the Author. *Vide* American Journal of the Medical Sciences, January, 1861.

in acute pleuritis. It proceeds, certainly in most cases, from the pleuritis developed in conjunction with the pneumonitis. As a rule, the intensity of the pain is in proportion to the amount of coexisting pleuritis; but it is true alike of pleuritis thus developed as a complication and when it occurs primarily that it is sometimes attended with little or no pain. Cases of pneumonitis differ considerably as regards this symptom; it may be quite prominent, or present in a moderate degree, or altogether wanting. The pain is usually referred to a circumscribed space at or near the nipple of the affected side. This limitation of the pain is a point distinctive of pneumonitis as compared with pleuritis.

Cough is usually present at, or soon after, the invasion. It is more or less prominent. It is sometimes wanting. It is painful in proportion as pain is a prominent symptom irrespective of the cough. The cough is frequently accompanied by expectoration. The matter at first expectorated is scanty, transparent, and viscid; and, in a certain proportion of cases, it soon assumes characters which are highly distinctive of the disease. It becomes semi-transparent, adhesive, and has a reddish tint like that of iron rust; hence it is commonly known as the rusty expectoration. This appearance is due to a small quantity of blood which has become intimately mixed with the matter in its passage from the smaller to the larger bronchial tubes. The adhesiveness is such that when a considerable quantity has accumulated, it adheres so closely to the bottom of the vessel as to remain when the vessel is inverted. The rusty expectoration is by no means uniformly present. Sometimes it is semi-transparent and adhesive without the reddish tint. It has sometimes a yellowish tint as if mixed with a little bile, which, however, is not the fact. It sometimes contains blood in abundance; and when the blood is of a dark color it gives rise to what is called the prune-juice expectoration. It is to be borne in mind that expectoration, in some cases of pneumonitis, is entirely wanting.

Febrile movement occurs with the invasion, together with pain in the head, loss of appetite, thirst, prostration, heat of skin, etc. The pulse varies much in frequency in different cases, ranging from 80 to 120, and is more or less full and hard. The thermometer in the axilla indicates more or less increase of heat, the increase, in mild cases, not exceeding 104° F.; an increase above this amount always denotes great severity of the disease. A sudden increase of temperature denotes the invasion of a new lobe or some intercurrent affection. Cases differ greatly as regards the symptoms of general or constitutional disturbance, the system being much more tolerant of the disease in some persons than in others.

The respirations are increased in frequency. This may depend on the pleuritic pain if it be marked, and also on the interruption of the function of hæmatosis in the portion of lung affected.

These are the important symptoms belonging to the clinical history at the commencement and during the first stage of the disease. During the stage of solidification, the symptoms undergo some changes. Pain, if it have existed, diminishes or ceases. Cough and expectoration continue, but the cough is less hard and painful, and the expectoration is effected with more facility. The matter expectorated loses its rusty appearance, becomes opaque, less adhesive, and more abundant. It is now the expectoration of resolving bronchitis. It is furnished chiefly by the bronchial tubes within the affected portion of lung, and is abundant in proportion as the bronchial mucous membrane is involved in the inflammation. On microscopical examination of the sputa, fibrinous casts of the minute bronchial tubes may be found. The febrile movement continues, but with

diminished intensity. The pulse in this stage may be small and deficient in strength, especially if more than one lobe be involved, owing to the obstruction to the pulmonary circulation, which diminishes the quantity of blood received from the lungs by the left auricle; and owing also to the amount of material withdrawn from the blood and deposited in the air-cells. The respirations are still increased in frequency in consequence of the solidified portion of lung taking no part in the respiratory function.

These are the modifications of the symptoms, assuming a single lobe only to be affected and that the course of the disease is favorable. The invasion of another lobe is rarely accompanied by a chill. The febrile movement persists or is increased, and the respirations become more frequent, accompanied perhaps by labor of breathing, marked dilatation of the alæ nasi, and dyspnœa. The affection, however, of an entire lung does not always give rise to symptoms denoting great gravity of disease. The febrile movement is not always intense, and may be slight; the respirations may be but little increased in frequency; cough and expectoration may be not only not prominent but even wanting, and the system may be but little disturbed. These remarks will also apply to double pneumonitis.

The symptoms during the stage of resolution denote progressive improvement. The febrile movement diminishes and ceases. The cough and expectoration become less and less, the respirations resume their normal frequency, the appetite returns, the strength is increased, and, in short, convalescence is declared. If, however, the disease pass into the stage of suppuration, the symptoms denote an unfavorable course. The pulse becomes more and more frequent and feeble. The expectoration is abundant and purulent. The respirations are frequent. The strength of the patient fails, and death takes place by asthenia, the accumulation of morbid products in the air-tubes frequently contributing to the fatal termination.

There are certain symptoms belonging to the clinical history of pneumonitis, which are not included in the foregoing sketch of its symptomatology. One of these relates to the urine. While the process of exudation is going on, and after solidification has taken place, until resolution begins, the chlorides frequently are greatly diminished, or disappear from the urine. This is ascertained by adding a solution of the nitrate of silver, having previously added a few drops of pure nitric acid. This delicate test shows the presence of a small quantity of the chlorides in the form of a cloudy precipitate. During the period just stated, if the chlorides be deficient or absent, the addition of the nitrate of silver produces little or no effect upon the urine. The precipitate is manifest as soon as resolution commences, and increases until the condition of health in this regard is gained. The disappearance of the chlorides from the urine is not peculiar to pneumonitis. It is observed in other diseases. It is not, therefore, a diagnostic criterion of the disease, but it constitutes evidence either that the exudation is going on, or that resolution has not begun. It is stated that the chlorides are found in abundance in the matter expectorated during the time of their disappearance from the urine. The quantity of urine is in general more or less diminished. The urea eliminated exceeds the amount in health, and, owing to the diminished quantity of water, the urates are often deposited in abundance when the urine becomes cold. The increase of urea denotes an abnormal secondary or destructive assimilation. It is not uncommon for the urine to contain a trace or a moderate quantity of albumen. The presence of albumen is probably due to the systemic venous congestion dependent on the over-accumulation of blood

in the right cavities of the heart. Albumen in abundance in the urine denotes coexisting renal disease.

Delirium not infrequently occurs in acute pneumonitis. It may be mild, and merely incidental to high febrile movement. But it is sometimes a prominent symptom. It may be active, the patient attempting to get out of the bed, resisting efforts of restraint, and perhaps using violence; or it may be of the low, incoherent, muttering kind, such as occurs in typhoid fever. Delirium is more apt to occur if the upper lobe be affected, than if the affection be limited to the lower lobe. It is evidence of gravity of disease in proportion as it is prominent, active, and persisting.

A circumscribed redness of one or both cheeks, the margins of the redness being abruptly defined, is frequently observed, and if the hectic flush of pulmonary tuberculosis be excluded, is quite distinctive of acute pneumonitis. When confined to one cheek, it does not follow, as was formerly supposed, that the pulmonary inflammation is seated on the same side. It is not uncommon for an herpetic eruption to occur upon the face, more especially around the mouth.

Slight jaundice is an occasional concomitant. Its occurrence is probably accidental. At all events, it is not associated often enough to show any pathological connection between pneumonitis and hepatic disease. Owing to the accumulation of blood in the right cavities of the heart, and the consequent congestion of the systematic veins, the liver sometimes becomes more or less enlarged.

The occurrence of abscess and gangrene is accompanied by symptomatic phenomena denoting these events. The collection of pus in an abscess leads to a sudden and copious purulent expectoration, if the life of the patient be sufficiently prolonged; and the existence of a cavity may be determinable by physical signs. This is a grave event, but it by no means necessarily renders the disease fatal. It occurred in 4 out of 133 cases, which I recorded and analyzed, and two of these four cases ended in recovery. I have notes of a case, in addition to the four cases just referred to, in which a series of purulent collections were expectorated, and the recovery was complete. The infrequency of gangrene is shown by its having occurred in but one of 133 cases. The disease proved fatal in that case. Since the analysis of these cases, I have known gangrene to occur, to a limited extent, in a case which ended in recovery. Its occurrence is shown by the characteristic fetor attending expectoration, together with the appearance of decomposed pulmonary tissue in the matter expectorated.

The combination of other affections with acute pneumonitis will, of course, involve the addition of symptoms derived from the former. In malarious districts it may be conjoined with periodical fever. This is a most important complication as regards danger and therapeutical indications. The existence of the pneumonitis may serve to interrupt, to a greater or less extent, the regular succession of periodical paroxysms, and the latter may tend to obscure the phenomena of the pulmonary affection. Pneumonitis occurring in the intemperate is liable to lead to the development of delirium tremens. The complication is always serious, and is important with reference to treatment. It occurred in 8 of 133 cases. Pericarditis is another grave complication. This occurred in 8 of 133 cases.

The supervention of certain symptoms is expressed by the term *typhoid pneumonitis*. This term denotes the existence of general symptoms analogous to those which belong to typhoid fever, of which the most prominent is low, muttering delirium. A distinction is here to be made

between typhoid pneumonitis and typhoid fever with pneumonitis as a complication. Pneumonitis is liable to be developed in the course of typhoid fever, the latter being the primary affection; but in the so-called typhoid pneumonitis, the latter is the disease, certain of the typhoid phenomena being superadded. In other words, the typhoid state may be developed in connection with pneumonitis, as with other local affections, but this typhoid state does not involve the essential fever designated as typhoid.

The duration of acute pneumonitis, when uncomplicated, varies within pretty wide limits. Dating from the attack to the time when the patient could be pronounced convalescent, in 30 cases, the shortest was 5, and the longest 23 days. The mean duration was a fraction over 12 days. In 14 fatal cases, the shortest duration from the attack to the time of death, was 3, and the longest 20 days, the mean duration being a fraction over 10 days.

A notable decrease of temperature sometimes precedes the fall of the pulse and improvement in other symptoms; and the defervescence in this disease, if it be uncomplicated and pursue a favorable course, is usually rapid. The pulse during convalescence is not unfrequently below the normal frequency, falling in some cases to forty per minute.

Pathological Character.—Acute pneumonitis is an inflammation affecting a structure reckoned as a mucous tissue, but differing materially from the membrane lining the bronchial tubes, in respect of both anatomical composition and function. Inflammation in this situation is characterized by an exudation which does not lead to the production of new tissue and adhesions, as in pleuritis; which is not exfoliated and expectorated, in this respect differing from the exudation of lymph on other mucous surfaces, but which is removed by absorption, and sometimes absorbed with great rapidity. The exudation in pneumonitis, doubtless, comes from the blood circulating in the branches of the pulmonary artery.

Causation.—Statistics show that no period of life involves either exemption from, or a notable proclivity to, acute lobar pneumonitis. It occurs under 5 years of age, but not frequently. Cases are less infrequent between the ages of 5 and 10. Of 118 cases, the patients all were over ten years of age, 13 were under 20; 44 between 20 and 30 years; 37 were between 30 and 40 years; 17 were between 40 and 50 years; 7 were between 50 and 60 years, and in no case was the age over 60. Cases, however, occur after the age last named. Cases occur much oftener among males than females. The analysis of my cases with reference to occupation, does not show that any particular calling predisposes to this disease, but the proportion of laborers engaged in out-door work over those employed within doors, shows that they are most liable to the disease who are exposed to the vicissitudes of the weather. Not infrequently the attack is fairly attributable to some unusual exposure, such as working in the cold and wet, or sleeping out of doors at night. The large proportion of hospital cases in which patients are addicted to excessive drinking shows that causative influences proceed from intemperance. In 10 of 37 cases in which the habits were noted, the attack followed a debauch. It is questionable whether the abuse of alcohol acts directly as a cause, or whether the disease may not be due, in a great measure, to circumstances incidental to intemperance, such as exposure to cold, etc.

The association of periodical fever and pneumonitis has already been adverted to. My observations do not show the existence of any patho-

logical connection between these affections. There does not seem to be ground for the conclusion that persons subject to intermittent fever are thereby more prone to pneumonitis, nor that the latter affection tends to reproduce an attack of the former. Their coexistence would appear to be due to the coincidence of the causes proper to each.

With respect to causative influences pertaining to other pulmonary affections, facts show that bronchitis does not tend to eventuate in pneumonitis. The same is true of pleuritis. Tuberculous patients are not particularly prone to the disease, and when it does supervene, it may, or may not, affect the upper lobe, in which the deposit of tubercle is most abundant. Certain pulmonary affections, viz., emphysema, asthma, and chronic pleuritis, are so infrequently associated with pneumonitis as to show that, instead of involving a predisposition to this disease, they afford more or less protection against it. Pneumonitis is not often developed in persons affected with organic disease of the heart.

Pneumonitis occurs as a complication of other than pulmonary diseases. It is not infrequently developed in the course of typhus and typhoid fever, and in rubeola. Degenerative affections of the kidneys have been supposed to stand in a causative relation to it. My experience does not furnish evidence of such a relation. In not one of the 133 cases analyzed was the disease preceded by albuminuria. I must, therefore, consider it doubtful whether pneumonitis is to be reckoned among the consecutive affections dependent on disease of the kidneys.

It occurs in certain seasons of the year in preference to other seasons. It occurs everywhere much oftener during the winter than during the summer months, and in our Northern States cases are more numerous in the spring months than at any other season. Forty-nine cases recorded at Buffalo were distributed among the different months as follows: January, 7; February, 2; March, 13; April, 9; May, 3; July, 3; August, *none;* September, 2; October, 1; November, 1; December, 5. At New Orleans, cases are most numerous during the winter months. The analysis of 296 cases, by Grisolle, shows the largest number of cases in February, March, April, and May, in Paris, the relative proportion of cases in June, August, September, and October being small.

In this country the disease occurs in the Middle and Southern, much oftener than in the Northern States. It prevails much more in some years than in others. In sections of the Southern States it prevails at times sufficiently to be considered as endemic. It is emphatically the prevalent disease during the winter months in these States, and, effecting especially the negro population, often proves the scourge of the sugar and cotton plantations of the South. It is a severer disease in the southern sections of the country than at the North, being more liable to extend beyond a single lobe, and proving fatal in a larger proportion of cases. This liability is greater, in the same district, in some years than in others. In some years, also, there is an unusual tendency in the disease to attack primarily an upper lobe. Such a tendency is manifest at the time of writing these remarks. Within the last two months (October and November) in hospital practice, I have met with five cases in which the disease has been limited to an upper lobe, being about one-half the cases which have occurred under my observation during this period.

In a large proportion of the cases of acute pneumonitis, the disease is developed spontaneously; that is, it is not referable to any obvious causative agency. An adequate, internal cause, of course, always exists, but its nature and source are not understood. Nor, indeed, are we able, with our present knowledge, to explain the development of the disease when it

appears to follow an obvious cause, viz., exposure to cold. It is probable that the latter acts only as an exciting cause, co-operating with a diathetic condition, or predisposition. Finally, the disease may be produced traumatically by injuries inflicted on the chest, and, thus produced, the inflammation rarely extends beyond a lobe, and may extend only over a portion of a lobe.

Diagnosis.—Acute pneumonitis, in some cases, is accompanied by symptoms which are highly distinctive. If a patient be seized with a chill, followed by febrile movement, together with a pleuritic stitch referred to a circumscribed space near the nipple, and the characteristic rusty expectoration occur, the diagnosis is readily made without the aid of physical signs. But these symptoms are by no means constantly present. The disease is not infrequently entirely latent as regards diagnostic symptoms, and it is often overlooked by those who do not employ physical exploration. Even if its existence be revealed by symptoms, without signs, the situation and extent of the affection can only be ascertained by means of the latter. With the aid of signs, the diagnosis, in the great majority of cases, is made without difficulty.

In the first stage, the signs on which the diagnosis is to be based are, slight or moderate dulness on percussion, and the crepitant rale. The latter, if persistent and well marked, is almost pathognomonic. Care must be taken, however, not to confound this rale with the subcrepitant, its distinctive characters being its fineness, dryness, and limitation to inspiration. With a distinct appreciation of these characters, it should never be confounded with the subcrepitant rale, which, however fine, is a moist, bubbling sound, and liable to be heard in expiration as well as in inspiration. These two rales sometimes exist in combination.

But the crepitant rale is not uniformly present. In its absence, a positive diagnosis may require some delay, until a sufficient number of lobules are solidified to give rise to an appreciable modification of the respiratory murmur. The modification is that which I have described under the name broncho-vesicular respiration;[1] a modification approximating, more or less, toward the bronchial or tubular respiration. With the occurrence of this modification, the dulness on percussion becomes more marked. In most cases, if the disease be observed from the beginning, the signs of the second stage are soon declared. In hospital practice, and in many cases in private practice, the disease has already advanced to this stage when the patient is first examined.

When the solidification has become sufficient in degree, and has extended sufficiently over the affected lobe to furnish the signs of that condition, the diagnosis, if it have not been already fully made, is rendered clear by the presence of these signs. Bronchial respiration, bronchophony, and whispering bronchophony are the signs denoting the condition of solidification. They are first manifested over a limited portion of the affected lobe, and are thence diffused over its whole extent, either quickly or gradually, according to the rapidity or slowness with which the whole lobe becomes solidified. The progress of the second stage may be determined by the diffusion of these signs. They are generally all present, but if one be wanting, the others will be likely to be present; it is exceedingly rare for all to be absent. Dulness on percussion is now marked, amounting, perhaps, nearly or quite to flatness. This dulness or flatness extends over a space

[1] *Vide* Physical Exploration of the Chest and the Diagnosis of Diseases affecting the Respiratory Organs. Second Edition. Henry C. Lea, 1866.

corresponding to that occupied by the solidified lobe; or, percussing anteriorly, the boundary line separating the dulness or flatness from the pulmonary resonance, is found to pursue a course coincident with the situation of the interlobular fissure, viz., obliquely upward and outward from the fourth or fifth costal cartilage toward the axilla. And this boundary line is the same whether the patient be sitting or lying upon the back. This is assuming that the pleural cavity does not contain liquid effusion, which, if it exist, is determined by the signs indicated in connection with the diagnosis of simple pleuritis. The crepitant rale, if it have existed in the first stage, may continue, more or less diminished, during the second stage, or it may disappear after the affected side has become solidified. The moist and dry bronchial rales are liable to be heard in this stage.

The invasion of a second or third lobe is denoted by dulness on percussion and the auscultatory signs of solidification, the crepitant rale rarely occurring in the lobes which become secondarily attacked. By means of the signs of solidification, viz., broncho-vesicular and bronchial respiration, and bronchophony with the loud and whispered voice, the extension of the affection to other lobes, in addition to the one first invaded, is speedily ascertained. If the upper lobe become solidified, it is sometimes flat on percussion, and sometimes it yields a tympanitic resonance which occasionally has an amphoric intonation.

For an account of the distinctive characters of the signs which have been named, and a fuller exposition of percussion and auscultation, together with the other methods of exploration in their application to the diagnosis of this as well as other pulmonary affections, the reader is referred to works which treat professedly of the subject. With a proper practical knowledge of the signs, the existence of the disease, the amount of lung involved, and the anatomical condition of the affected portions, are readily and accurately determined.

The commencement of resolution and its progress from day to day are shown by modifications of the signs denoting solidification. The bronchial respiration gives place to the broncho-vesicular, and the latter progressively approaches more and more to the normal vesicular murmur, into which it becomes finally merged when the resolution is completed. The characters of bronchophony are gradually lost. Dulness on percussion becomes less and less marked, but some degree of dulness over the affected lobe or lobes continues for some time after the auscultatory signs show the exudation to have been removed. During the progress of resolution, the subcrepitant rale is frequently heard, and sometimes the crepitant rale reappears, constituting the crepitant rale redux.

If the disease pass into the stage of suppuration, the dulness or flatness on percussion continues, and the moist bronchial rales, due to pus in the air-tubes, are prominent. The auscultatory signs of solidification continue, but are less marked. If abscess of the lung take place, and the patient's life be prolonged until a discharge of the pus into the bronchial tubes occur, cavernous respiration may become well marked.

A coexisting liquid effusion, occurring exceptionally, is shown by signs already noticed. Under these circumstances, the affected side may be dilated, with obliteration of the intercostal depressions, and obvious contraction of the chest may follow recovery.

Prognosis.—The prognosis, in cases of acute pneumonitis, will depend on the extent of lung involved, the diseases with which it may be connected as an intercurrent affection, its complications, the previous constitution of the patient, etc. These circumstances will affect the gravity

and danger to such a degree that, in respect of the probable termination, different cases differ as much as if they were cases of different forms of disease. Occurring as a primary disease, limited to a lower lobe, remaining uncomplicated, and the person affected having a fair constitution, the intrinsic tendency is to recovery; indeed, recovery is not only the rule, but the exceptions are exceedingly unfrequent. Of sixty-nine deaths out of 750 cases reported by Dr. Dietl, of Vienna, in not one was the disease devoid of complications. Of the 133 cases which I have analyzed, in only two of the fatal cases was the disease limited to one lobe, and not complicated or associated with other important affections. In one of these two cases the inflammation was seated in an upper lobe, and eventuated in abscess. In the other case the absence of complications was predicated on the examinations during life, a post-mortem examination not having been made.

Even if more than one lobe be involved, provided the disease be primary and uncomplicated, a favorable termination may reasonably be expected in a subject not enfeebled by age or other causes. I have known recovery to take place in a case in which an entire lung was involved, and the patient situated under as unfavorable hygienic circumstances as could well be imagined. In the case referred to the patient was attacked when working alone in a shanty, there being, at the time, two inches of water on the ground. The case occurred, during the winter season, in the swamp near New Orleans. After the attack he was unable to leave the bed for any purpose for a week, and during this time he was entirely alone. He had a quart of brandy, which he drank during the week. His habits, as he stated, were temperate. At the end of a week he was visited by some one (not a physician) who gave him thirty grains of calomel. After this he remained alone for ten days. A friend at length came to him, gave him some doses of quinia, and removed him first to his own house, and afterward to the Charity Hospital of New Orleans. The physical signs, on his admission into the hospital, showed pneumonitis affecting the whole of the right lung, and resolution progressing. He remained in hospital six days, convalescence going on rapidly, and at the end of that time he was well enough to be discharged.

The gravity and danger, then, in cases of this disease, proceed, not so much from the disease *per se*, as from coexisting affections and other incidental circumstances. Developed in the course of continued fever, measles, or other diseases, it may lead to a fatal termination. In aged and feeble persons it may end fatally without any coexisting disease, especially if more than a single lobe be involved. Occurring in persons affected with organic disease of the heart, it is likely to prove a serious affection. I have known it to destroy life in the first stage when developed in this connection. The pulmonary symptoms are rendered more severe and the danger increased by antecedent emphysema.

The complications which are apt to render it fatal are pericarditis, intermittent fever, and delirium tremens. These complications invest cases with much gravity and danger, but recovery takes place, in a certain proportion of cases, notwithstanding their existence. The gravity and danger from these complications are of course greater if the disease invade more than a single lobe.

There is a liability in the course of this disease to a fatal accident which claims especial notice, and which has not been sufficiently considered. Reference is had to the coagulation of fibrin in the right cavities of the heart. I have been led to regard this as an event of not unfrequent occurrence in fatal cases of pneumonitis. It is apt to occur in cases in which

an entire lung becomes involved, or in cases of double pneumonitis. In such cases, the obstruction to the passage of blood through the lungs, caused by the presence of the exudation, involves an over-accumulation of blood within the right cavities of the heart. The right ventricle and auricle are enfeebled by distension, and this condition, in conjunction with the increase of fibrin in the blood (hyperinosis), leads to coagulation. On examination after death in cases in which this accident has taken place, the right ventricle is found to contain a dense white clot closely intertwined with the tendinous cords, and perhaps adherent to the ventricular walls, sending prolongations into the pulmonary artery and through the tricuspid orifice into the auricle. A clot may also be formed in the auricular portion of the latter cavity. These clots are formed during life, and prove the immediate cause of death. Their formation may sometimes be determined with much confidence by the symptoms during life. In a case presenting no symptoms which denote imminent danger, a sudden change takes place for the worse; the circulation is notably disturbed, as shown by frequency, feebleness, and irregularity of the pulse; the respiration becomes notably embarrassed, the expression haggard and anxious —the patient falls speedily into a moribund state, and this unexpected change is not connected with an extension of the disease to a new lobe or any newly-developed inflammatory complication. Under these circumstances the formation of a heart-clot is highly probable, and the probability of this accident is rendered still stronger if a newly-developed cardiac murmur be discoverable.

The following synopsis of a case which I observed in March, 1865, illustrates the sudden development of symptoms of great gravity, on a secondary invasion of a lobe of the opposite lung, or the occurrence of double pneumonitis:—

The patient, a banker, about sixty years of age, was a man of delicate constitution, of temperate, regular habits, and extremely careful in everything relating to his health. He was attacked with pneumonitis March 28, the lower lobe of the right lung being the seat of the disease. He appeared to be doing well, the affected lobe, however, presenting, well-marked, the signs of solidification, when, on the evening of April 1st, the fifth day of his illness, there was a sudden and notable change as regards the general symptoms. I saw him soon after this change occurred, and found the pulse very frequent and feeble, the skin cold and covered with a clammy sweat, the respirations spasmodic with tracheal rales. There was profound coma, the pupils scarcely responded to light, and liquid poured into the mouth was not swallowed. The patient was seen by Dr. Charles F. Heywood; we considered him as moribund, and there seemed to be scarcely an encouragement in the symptoms of the case to undertake to avert impending death. After persevering efforts we succeeded in making him swallow a tablespoonful of brandy. In half an hour another tablespoonful was given with less difficulty. After this he swallowed readily, and brandy was given at short intervals. After the lapse of several hours consciousness gradually returned, and all the symptoms denoted improvement. His prostration, however, was such that no examination of the chest was made until April 3d, when were found the signs denoting invasion of the lower lobe of the left lung. Under supporting measures of treatment he passed safely through the double pneumonitis, and he has better health since his recovery than for a long time prior to his illness. Since this case was observed, I have met with cases in which a primary invasion, occurring in aged persons, produced such a degree of prostration and disturbance of the heart's action, that death by rapid asthenia

seemed imminent, life being apparently saved by free alcoholic stimulation and digitalis.

As regards anatomical changes pertaining to the lungs, gangrene, abscess, and the suppurative stage of the disease render the prognosis extremely unfavorable. Yet I have known recovery to take place in cases in which the symptoms denoted the occurrence of these events.

Symptoms which are unfavorable as prognostics are the following: Frequency and feebleness of the pulse, irrespective of the formation of a heart-clot. Great frequency and labor of respiration. Lividity of the prolabia and face. An abundant purulent or muco-purulent expectoration. Bloody, dark-colored sputa, commonly known as the prune-juice expectoration. Active, violent delirium. Low, muttering delirium, with prostration and subsultus tendinum, constituting the typhoid state. Cases presenting the symptoms last stated are often distinguished as cases of typhoid pneumonitis.

In the majority of fatal cases of acute pneumonitis, death takes place by asthenia in combination with apnœa, the former predominating. Death purely by apnœa may occur if two or three lobes become rapidly involved, but its occurrence is rare. The occurrence in some cases of an abundant pleuritic effusion, increases the danger from apnœa. So, also, its occurrence in persons affected with emphysema, and in cases of pertussis. In general, life is not lost in consequence of the extent of interference with respiration, but, owing to concomitant affections or other circumstances, the vital powers give way, and the patient dies from exhaustion. This is an important fact in its bearing on therapeutical indications.

When convalescence takes place in this disease, it generally progresses until the recovery is complete. The tendency to pass into a chronic form is exceedingly slight. Nor is there a tendency to relapse. It is certainly rare for tuberculous disease to become developed as a sequel of pneumonitis. When phthisis follows, the deposit of tubercle probably existed prior to the pneumonitis. When the upper lobe is primarily attacked, it has been supposed that the prior existence of tuberculosis may be inferred. There may be some ground for this inference, but I have repeatedly known the inflammation to be limited to the upper lobe in cases in which the anterior and subsequent history furnished no evidence of phthisis.

CHAPTER V.

Treatment of Acute Lobular Pneumonitis. Pneumonitis in Young Children. Circumscribed Pneumonitis. Chronic Pneumonitis—Induration—Sclerosis and Cirrhosis of the Lung. Pigment, or brown induration. Anthracosis. Siderosis. Lobular Pneumonitis—Atelectasis and Collapse of Pulmonary Lobules. Pleurodynia and Intercostal Neuralgia.

THE different stages of acute pneumonitis furnishing different therapeutical indications, the treatment of each stage is to be considered separately.

The question whether the disease may be arrested, relates to the first stage. Measures which have heretofore been considered as abortive, and which are still, perhaps, so considered by some, are bloodletting, cathartics,

and other remedies entering into the so-called antiphlogistic method of treatment. Experience has abundantly shown that these measures are not to be relied upon for the arrest of this, more than other inflammations. Admitting that they sometimes succeed, the probability of success is so small as not to warrant their employment under circumstances which will be likely to render their operation hurtful should they not prove successful. The objects of treatment, then, in the first stage, are to diminish the intensity of the inflammation, to relieve symptoms, and place the system in a condition to tolerate the disease.

As regards bloodletting, its employment is to be regulated by the general considerations presented in Chapter II., Part II., to which the reader is referred. It is admissible in certain cases as a palliative, and, perhaps, to some extent, a curative measure, in view of the promptness of its operation. The circumstances which warrant its employment are: high febrile movement, the pulse more or less resisting compression, and the condition of plethora, or at least a robust constitution. It is contra-indicated whenever the febrile movement is not marked, when the pulse is frequent and weak, and if the patient be anæmic or have a feeble constitution. The relief of pain and embarrassment of breathing by bloodletting is often immediate and marked. The efficiency of this measure as a palliative is due in part to its effect on the general circulation, and to the diminution of the functional labor of the lungs; but the relief may be in part explained by the effect in diminishing congestion of the portions of the pulmonary organs not inflamed (the collateral fluxion of Virchow), and also by the effect in lessening the accumulation of blood in the cavities of the right side of the heart. In most of the cases, however, in which bloodletting would be admissible, provided the same ends could not be secured by other means, the latter are to be preferred. These consist of depletion by saline purgatives, and sedative remedies. After the operation of a saline purgative, if the skin be hot and the pulse frequent, tartar-emetic or some antimonial preparation may be given as a nauseant sedative; but the doses should not be carried to the extent of producing marked or distressing nausea. The veratrum viride may be given under the same restriction. These remedies are not called for if the symptoms be not urgent, and they are contra-indicated by feebleness or a tendency to depression. Aconite is an effective sedative remedy, and is to be preferred to the sedatives just named whenever it be desirable to avoid the depressing effects of the latter. Opium may be given with propriety and advantage in the first stage, in doses sufficient to relieve the pain and tranquillize the system. Blisters are injudicious, but dry cups, sinapisms, or stimulating liniments may be employed. Stupes, or warm fomentations, applied to the chest, are useful. In many cases, a saline purgative followed by some form of opium, the latter continued at intervals, together with soothing applications to the chest, will meet the indications pertaining to the first stage. Niemeyer extols cold applications over the part of the chest corresponding to the affected portion of the lung, by means of napkins which have been dipped in cold water, and which are to be renewed every five minutes. He states that his advocacy of this measure is based upon the favorable effect in a large number of cases. Generally, after a few hours, patients are sensible of relief; and often both the respiration and the pulse become less frequent. Not unfrequently, the temperature of the body is notably reduced. In some cases, however, patients complain of the application, and, if so, it should not be continued. He does not claim for this measure that it arrests the disease, but that the duration of the disease may be abridged

by it, and that it is valuable as a palliative measure. It by no means follows that because warm applications are useful, the application of cold is not also useful, or *vice versa;* each may have a favorable effect, the *modus operandi* of each differing from that of the other. Warm applications soothe and act as revulsives; the application of cold diminishes the determination of blood to the part, and relieves pain by obtunding the sensibility. The application of cold water to the entire surface of the body, by means of the cold bath or by wrapping the body in a wet sheet, has been found safe and useful in acute pneumonia as in other acute inflammations. If resorted to, its employment is to be regulated by the circumstances stated in connection with the treatment of acute pleuritis. *Vide* page 153.

The treatment in the second stage has reference to the promotion of resolution, palliation of symptoms, and supporting the powers of the system. Bloodletting in this stage is not admissible, and depletion by means of salines is not called for. It is not an object to divert the blood from the solidified lung, for the exudation has already deprived it of blood; and the amount of exudation involves the withdrawal from the blood of a pound or so of solid matter, even when the inflammation is limited to a single lobe. Can we give remedies to excite absorption, and thus shorten the duration of the second stage? Laennec extolled the use of tartar-emetic in large doses for this object, after the plan of Rasori. But Laennec was not aware how speedily absorption sometimes begins after exudation has reached its maximum, and how rapidly the resolving process goes on in some cases, irrespective of any treatment; for, in his day, the natural history of this disease had not been studied. It is reasonable, therefore, to conclude that he mistook for the effect of this remedy the occurrence and progress of resolution due to the intrinsic tendency of the disease. With our present knowledge of the course of the disease in cases in which no active measures of treatment are employed, and after a large experience of the value of tartar-emetic as a sorbefacient, its utility in this way is, to say the least, doubtful. The same remarks are applicable to mercury given with a view to affect the system. I have now for many years ceased to employ these remedies for the purpose under consideration, and have seen no reason to be dissatisfied with discontinuing their use. The use of iodine externally or internally is not open to the objections of tartar-emetic and mercury, on the score of doing harm if it be not useful. A convenient mode of employing iodine is to apply the tincture to the affected side.

Repeated applications of the tincture of iodine will secure a sufficient amount of counter-irritation, if any be desirable. Blisters are not advisable on account of the general disturbance which they are apt to occasion, and their interference with physical examinations of the chest. It is the custom in Bellevue Hospital to cover the chest with an oiled muslin jacket. This contributes to comfort by keeping the surface moistened with perspiration; and if a flannel covering be added, all the advantages of a poultice or water-dressing are thereby secured. If pain and soreness continue in this stage, stupes with warm water only, or with some stimulating liquid, as the spirits of turpentine, will afford relief. The latter will not be required if the tincture of iodine have been applied.

Opium is a most valuable remedy in the second as in the first stage. It is indicated, not only by the continuance of pain, but by vigilance, restlessness, and symptoms denoting constitutional disturbance. I have repeatedly observed a rapid and notable diminution of the frequency of the pulse and of the respirations, with refreshing sleep and a condition of comfort, to follow full doses of opium. This remedy has the advantage

of not doing harm if it fail to do the good which we expect from it. The free use of opium does not delay the commencement nor retard the progress of resolution. An accumulation of mucous secretion in the bronchial tubes contra-indicates the use of opium in full doses.

Remedies to promote expectoration, as a rule, are not indicated. The use of remedies of this class is based on the erroneous idea that the matter of exudation is expectorated. Clinical observation shows that the removal of this matter may go on with great rapidity without any expectoration. The expectoration in the second stage of the disease is due to bronchitis usually limited to the affected lobe or lobes. The mucous products rarely accumulate in the bronchial tubes to an extent to occasion inconvenience, except as a consequence of a degree of exhaustion sufficient to render the muscular power inadequate to efficient efforts of expectoration; and, under these circumstances, expectorant remedies will not afford relief.

Sedative remedies, such as the tartar-emetic, in small doses, aconite, and the veratrum viride, are admissible in this stage, if there be considerable or high febrile movement, without a tendency to asthenia. They should be cautiously given, so as not to incur risk of constitutional disturbance or depression.

To support the powers of life is the leading general indication in the second stage. Resolution will be sure to begin and continue if the life of the patient be sufficiently prolonged. The danger is generally, not from the amount or persistence of the solidification of lung, but from failure of the vital powers before the resolution takes place. This disease belongs among those distinguished as self-limited; if uncomplicated and not attended by accidents, it runs a definite career ending in restoration, provided the powers of life hold out. These considerations, together with the results of clinical experience, enforce the importance of the supporting treatment.

The indication for supporting measures, as regards urgency, varies much in different cases. In general terms, it is urgent in proportion to the danger from asthenia. It should govern the treatment in cases sometimes characterized as asthenic, and whenever there are grounds for distrust of the adequateness of the vital powers to carry the patient safely through the disease. It is a serious mistake to defer supporting measures until the symptoms denote imminent danger from failure of the powers of life. If deferred so long, they will probably be too late. The observing and skilful practitioner will foresee and endeavor to forestall a degree of prostration attended with imminent danger. The constitution of the patient, his previous health, and his habits, are to be taken into account in judging early of the ability to sustain the disease. Other things being equal, in a warm climate patients are less able to sustain the disease than in cold or temperate climates; supporting treatment, therefore, is oftener and earlier called for in the former than in the latter. The plantation negro at the South is less able to sustain it than the white man, and, consequently, is more likely to need support. In cases which are distinguished as asthenic and typhoid, the reliance for successful management must be on supporting measures. These views are the more to be impressed because it is undoubtedly true that, until lately, the minds of medical men have been so much occupied with the means of subduing inflammation, as to overlook the fact that means employed for this end, not only often conflict with those which are more important for recovery, but may be positively injurious, if not, indeed, destructive to life. The attention has been directed too much to the disease and too little to the patient.

The supporting treatment embraces tonic remedies, alcoholic stimulants,

and nutritious diet. Of tonic remedies, quinia is to be preferred. It is not indicated in mild cases, but whenever there are grounds for anticipating undue depression of the powers of life, it may be given and continued during the progress of disease. Alcoholic stimulants form a very important part of the supporting treatment in this disease, as in all other diseases, whenever the great object is to keep the patient alive until the disease has reached the end of its career and advanced into the stage of resolution. The principle is the same as in the essential fevers; and here, as in the management of the essential fevers, alcoholic stimulants are indicated to an extent commensurate with the danger from failure of the vital powers. In certain cases of pneumonitis, as in typhus or typhoid fever, and other affections, there is often a remarkable tolerance of alcohol, and the only guide, as regards quantity, is the effect as manifested by the symptoms. No abstract rules can be laid down, applicable to all cases, but careful observation must furnish the rule proper to each individual case. Here, too, as in the continued fevers, because alcoholic stimulants are vastly important in some cases, it is not to be inferred that they are invariably indicated, nor that they can never do harm; on the contrary, if pushed to an injudicious extreme, they are as potent for evil as they are potent for good when judiciously used.

As regards the circumstances under which the use of alcoholic stimulants is to be commenced, they are always indicated as soon as evidence appears of any tendency to failure of the powers of life. And of this, the action of the heart, as represented by the pulse, is the best criterion. Feebleness, great frequency, and a pulse vibratory or thrilling but compressible, denoting increased activity but diminished power of the ventricular contractions—these are the characters which indicate supporting measures, of which alcoholic stimulants are an essential part. Given at first in small or moderate doses, the effect is to be watched, and the quantity increased in proportion to the urgency of the indication. The habits of the patient, as regards the habitual use of alcoholic drinks, are of course to be taken into account. Whenever the question arises, in the management of a case, whether alcoholic stimulants be advisable or not, it should be borne in mind that to begin earlier than they are required is far preferable to subsequent delay; for with proper care they can be suspended without any injury having been done, whereas the time lost by beginning too late cannot be regained.

Alimentation is an essential part of the supporting treatment. It is as important to nourish patients affected with pneumonitis as those affected with fever or any disease, whenever there is danger from failure of the vital powers. The statement that patients with pneumonitis should be encouraged to take nutritious food during the whole course of the disease is based on considerable experience, and alimentation should enter into the treatment in proportion as the symptoms denote a tendency to asthenia. Milk with farinaceous substances, with animal broths, should form the diet, thus combining a proper variety of alimentary principles. The desires and taste of the patient may generally be trusted.

These remarks on the supporting treatment are not specially applicable to pneumonitis, but apply alike to cases of any disease, the gravity or danger of which is manifested by symptoms denoting failure of the vital powers, and they will be referred to in connection with the treatment of other affections. As applied to pneumonitis, they relate chiefly to cases in which this disease is rendered grave or dangerous either by the extent of lung involved, or by coexisting affections. It will be borne in mind that in a large proportion of the cases in which the disease is limited to a

single lobe, and disconnected from other affections, there is little or no intrinsic tendency to a fatal termination. In such cases no active treatment is required, either with a view to lessen the intensity of inflammation or to support the powers of the system. Patients pass through the disease satisfactorily under simple palliative measures.

In cases of pneumonitis associated with intermittent fever, quinia should be given promptly and in efficient doses. The paroxysms should be arrested as speedily as possible; the patient may be placed in great danger by their repetition. The existence of pneumonitis and the degree of symptomatic febrile movement in no wise conflict with this important indication; indeed, so far from conflicting with it, the sedative effect of full doses of quinia may be useful, aside from the arrest of the paroxysms. In a malarious region, or if the patient have been subject to intermittent fever, it is judicious to forestall the possible development of the latter affection by moderate doses of quinia. The malarious cachexia impairs the power of resisting the disease; hence, it is more likely to prove fatal in malarious regions, even when uncomplicated with intermittent fever.

Cases of pneumonitis complicated with delirium tremens call for the pretty free use of opium, together with alcoholic stimulants and a nutritious diet. Delirium and vigilance, if protracted, are likely to lead to a fatal termination. Pericarditis, as a complication, adds greatly to the gravity and the danger; but, by perseverance in the judicious employment of supporting measures, the patient may be carried safely through this combination of diseases. The occurrence of gangrene furnishes an additional indication for support. Pneumonitis occurring in the course of the continued or eruptive fevers is to be treated by soothing and supporting measures. Depressing treatment by bloodletting, antimonial preparations, and purgatives, are very rarely, if ever, admissible under these circumstances.

During the progress of resolution, the principles of treatment which have just been presented are applicable until the improvement in the local and general symptoms, in connection with the physical signs, denote convalescence. When convalescence is established, there is little or no danger of a renewed attack. There is, therefore, no need of extreme precautions in order to prevent a liability to relapse. Experience shows that a solid, substantial diet may be entered upon as soon as the patient is fairly on the road to recovery, and that the recovery is more rapid than if the appetite be too much restrained. As a rule, ordinary wholesome, digestible articles of food may be allowed when they are desired by the patient. Permitting or encouraging the patient to sit up will be found not to retard recovery, but, on the other hand, apparently to hasten the progress of resolution. Early going out of doors is not objectionable.

If the disease proceed to the suppurative stage, purulent matter being either infiltrated or forming abscesses, the prognosis is extremely unfavorable, but perseverance in the employment of supporting measures is sometimes successful. It may be added, that timely and efficient support probably affords the best security against suppuration, which happily is extremely rare.

The liability to the formation of heart-clot in cases of pneumonitis suggests the important inquiry whether measures may not be employed to prevent this accident. Acting upon the conclusion, deduced by Dr. B. W. Richardson from a large number of varied experiments, that the liquid form of the fibrin in the blood is due to the presence of ammonia, I have for several years advised the carbonate or muriate of ammonia during the progress of the disease with a view to prevent coagulation. Of course, it

is difficult to obtain clinical proof of the protective efficacy of this or any other remedy. There can be no objection to the use of this remedy on therapeutical grounds, since it does not in any manner affect unfavorably the progress of the disease. It may be added that the conclusion just stated has been abandoned by Dr. Richardson. Dr. A. Patton, of Indiana, in a paper advocating the free use of this remedy throughout the disease, that is, from 5 to 10 grains every three hours, states that, of 96 cases in which this constituted all the medicinal treatment, in only two cases was the disease fatal.[1] It is probable that digitalis, given with a view to increase the power of the heart's action, is useful in preventing heart-clots. This remedy has seemed to me often signally useful when the action of the heart is feeble or irregular.

Acute pneumonitis, diffused over an entire lobe, sometimes involving a second lobe, and presenting after death the anatomical characters which have been described as belonging to this disease in the adult, occurs in young children, although infrequently as compared with its occurrence after this period of life. It is a much graver disease in young children than in adults, proving fatal in a large proportion of cases. From the absence of the subjective symptoms, and the difficulty of obtaining physical signs, the diagnosis is less easy, and the disease is not unfrequently overlooked.

The attack is sometimes accompanied by a convulsion. This may mislead by directing attention to the head. Dulness, drowsiness, or stupor sometimes accompanies the progress of the disease, and these symptoms may mislead in the same way, if the symptoms referable to the chest be not marked. The expectoration, being swallowed, cannot be observed in young children. As regards marked local symptoms, the disease may be latent in the child, as it frequently is in the adult. But, in a certain proportion of cases, the existence of sharp pleuritic pain is manifested by the expression, and, also, by the cry in acts of coughing, or whenever a deep inspiration is taken. A diagnostic symptom, of frequent occurrence, is a moaning or grunting sound with the expiratory act. Attention to this symptom is especially important, as it points very strongly to the existence of pneumonitis. Increased frequency of the respirations and dilatation of the nostrils show the existence of some pulmonary affection compromising the respiratory function. The respirations, in some cases, are very frequent, numbering 40, 50, 60, and sometimes even many more per minute. One or both cheeks may present a circumscribed flush. If the progress of the disease be unfavorable, lividity of the prolabia and face becomes marked; more or less acceleration of the pulse occurs, and the frequency, in some cases, is very great, amounting to from 150 to 200 per minute.

When the existence of some acute affection of the chest is declared by the symptoms, the differential diagnosis lies between primary pleuritis, capillary bronchitis, and pneumonitis. The first of these affections being extremely rare under five years of age, the problem is usually to decide between the last two. In making this decision, the physical signs are to be relied upon, and the reliance is also upon these for the diagnosis in cases in which the symptoms denoting an acute thoracic affection are not marked. The physical signs are generally available, with care and patience, nowithstanding the difficulty of exploring the chest in the young child.

The crepitant rale is oftener wanting in pneumonitis affecting the child than the adult, but it is present in a certain proportion of cases, and is, of

[1] Am. Journ. of Med. Sciences, Oct. 1870.

course, to be sought after. This sign belongs exclusively to pneumonitis, whereas the subcrepitant rale belongs to capillary bronchitis. If there be doubt as regards the discrimination between the crepitant and subcrepitant rale, it is to be borne in mind that capillary bronchitis is a bilateral disease, and the rale will be present in both sides; whereas, in the great majority of cases, pneumonitis in the child or in the adult is unilateral, and the rale will be limited accordingly to one side. Dulness on percussion is readily determinable in the child, and this is an important point in the differential diagnosis. Bronchial respiration and bronchophony may generally be obtained in the child by perseverance in auscultation, the cry answering for the voice. These signs do not belong to capillary bronchitis. In short, the diagnosis is to be based on the same signs as in the adult, but patient efforts may be requisite to obtain them. As regards primary pleuritis, the signs denoting effusion are available in the child as well as in the adult, and their absence warrants the exclusion of that affection.

The treatment of pneumonitis in children involves the same principles as the treatment of the disease in adults, with those modifications which therapeutical measures require in their application to infantile life. It is questionable whether bloodletting be ever advisable in young children, even when the diagnosis is clear in the first stage of the disease. As a rule, this measure is not to be employed, and the exceptions to the rule, if there be any, are few; depletion by salines should take its place. Antimonial preparations, if given at all, are to be prescribed with great caution, and, in general, other and less depressing nauseant sedatives are to be preferred. The veratrum viride, if given, should be prescribed in small doses, and its effects very carefully watched. Aconite, in children as well as adults, is a useful sedative in this affection. Blisters should not be employed. A sinapism or turpentine stupes may be applied to the chest, followed by a poultice or the water-dressing. Particular attention should be given to the latter, in order to see that either the entire chest or the whole of the affected side is covered with several thicknesses of flannel and a layer of oiled muslin. The spongio-piline is a good substitute for the poultice or water-dressing. Opium need not be withheld, but must be given with circumspection. Finally, as much depends, in severe cases, in the child as in the adult, upon the early, judicious, and persistent employment of supporting measures. In children, as in adults, under certain circumstances, there is a remarkable tolerance of alcoholic stimulants. I have notes of the case of a child of a medical friend (age fourteen months), presenting the utmost gravity of symptoms, the pulse 200 and the respiration 120 per minute, in which brandy was increased to at least an ounce hourly, and, under this amount of stimulus, the pulse fell rapidly to 124, and the respiration to 50 per minute, the carbonate of ammonia and a little morphia constituting the additional treatment. Recovery took place. This case is cited in illustration of the extent to which, in some cases, the employment of alcoholics may be carried. It does not follow that they are to be generally employed excessively or largely. The same rules are to be observed in treating cases of this disease in children as in adults, with a view, on the one hand, to secure the benefits of stimulants, and, on the other hand, to avoid the evils of their over-use.

Circumscribed Acute Pneumonitis.

Acute pneumonitis, when not incidental to an existing pulmonary affection, as a rule, extends over an entire lobe at least. To this rule, as already stated, there are exceptions. The exceptions are infrequent, yet perhaps

they are not so rare as is supposed, for, if much circumscribed, the affection is overlooked without a careful physical exploration, and even the signs may escape detection. One of my colleagues experienced a slight pain in the chest, and expectorated two or three rusty sputa. On careful examination by auscultation, the crepitant rale was discovered at the base of the chest, limited to a space not larger than half a dollar. This circumscribed pneumonitis, preceded by perfect health, did not prevent him from continuing his professional labors as usual. Such cases might easily be overlooked. But, in general, when pneumonitis is circumscribed, it is incidental to some previously existing pulmonary affection.

It is a not infrequent concomitant of tuberculosis. More or less of the lobules in proximity to the tuberculous product become inflamed. An examination of the chest, at this time, may disclose a crepitant rale within a limited area, and this rale, under these circumstances, is one of the accessory signs of phthisis. The exudation proceeding from the circumscribed pneumonitis renders the physical signs of solidification more marked and extensive than they had been found to be on previous examinations, and, after a time, when resolution has taken place, these signs diminish so as to represent simply the tuberculous affection. Cases exemplifying this statement have repeatedly come under my observation. The occurrence of such attacks of circumscribed pneumonitis will serve to account for changes, as regards the physical signs, which, if not understood, would seem to be inconsistent with the natural history of tuberculous disease. Circumscribed pneumonitis occurs in certain of the cases of so-called pyæmia, and is manifested, if death take place early, by nodules, more or less numerous, varying in size from that of a pin's head to a walnut, of a dark color, the appearances being due, not to extravasation of blood, but to deep congestion. These nodules, when situated near the surface, are conoidal in form, the pleural portion being the larger. They represent the first stage of inflammation; and, if life continue, they become the sites of the purulent collections which were formerly called, incorrectly, metastatic.

Inflammation excited by a wound of the lung, as when a musket or pistol ball passes through the chest, may be more or less circumscribed.

Whether primary or otherwise, pneumonitis limited to a circumscribed space claims only simple palliative measures and hygienic precautions. The treatment in cases of pyæmia is to be directed to the general disease.

Chronic Pneumonitis—Induration—Sclerosis and Cirrhosis of the Lung—Pigment, or Brown Induration—Anthracosis—Siderosis.

The term chronic pneumonitis is not here considered as embracing what has been commonly known as tuberculous infiltration of the lung. This statement is required, inasmuch as the latter is by some writers reckoned a variety of pneumonitis, and so named. This affection is considered in the first part of this work (see page 35), and in Part Second, Chapter X., under the name pulmonary tuberculosis. If it be designated pneumonitis, the adjective tuberculous should be prefixed, in order to distinguish it from other forms of inflammation of the lung, and, at the same time, to indicate a pathological connection, to say the least, with tubercle.

It has been seen that acute pneumonitis is characterized by the presence of inflammatory products within the pulmonary vesicles, cells, or alveoli. This characteristic, also, belongs to tuberculous infiltration. But, eliminating the latter from present consideration, cases occur in which, with

essentially the same kind of product within the air-cells, as in cases of acute pneumonitis, the symptoms and progress denote either a subacute or a chronic affection. Occurring as a complication of other diseases, pneumonitis is not infrequently a subacute affection. So, also, when primary, it is sometimes devoid of symptoms which denote acuteness; and yet the local morbid conditions, as determined by physical signs, extend over an entire lobe, and are as marked in degree as in acute cases. It is not very rare for patients to come to dispensaries for treatment in the second stage of the disease; and the disease may pass through its entire course without obliging the patient to keep the bed even for a day. On the other hand, in some exceptional cases, the acute symptoms disappear, but the solidification remains for many weeks, resolution at length taking place completely. The name chronic pneumonitis might, with propriety, be applied to the disease in such cases. A patient is admitted into hospital, having been confined to the bed for some time before admission. There are found the signs of solidification extending over the greater part or the whole of either an upper or a lower lobe. If the upper lobe be the seat of the affection, the disease is apt to be considered at first as tuberculous. But, after a time, the solidification is found to diminish, and, finally, at the end of one or two months, it has disappeared, the normal signs return, and the patient is discharged well. Such a history is of rare occurrence, but examples have fallen under my observation.

The name chronic pneumonitis, however, is applied to an affection quite different from that which exists in the cases just referred to. Exclusive of infiltrated tubercle, or tuberculous pneumonitis, the name is used to denote a morbid condition characterized by hyperthesia, or a morbid growth of the connective tissue which holds together the cells, vessels, and lobules of the lungs. It differs from the pneumonitis already considered in the absence of morbid products within the air-cells or alveoli. It is not an inflammation of the latter together with the bronchioles, but the morbid process is seated in the interstices of these and of the pulmonary lobules; hence the pertinency of the name given to the affection by Rokitansky—"interstitial pneumonitis." In its seat and character, it is affiliated with a morbid growth of the neuroglia constituting sclerosis of the brain and spinal cord, with cirrhosis of the liver, and with the fibroid or cirrhotic kidney. Corrigan described the affection, under the name "cirrhosis of the lung," in 1838. It has been called fibroid degeneration and fibrous induration of the lung; the latter term is still not infrequently applied to it.

As regards its pathological character, Bastian and others deny that it is inflammatory; and, with this view of its pathology, the name pneumonitis is, of course, inappropriate. Whether it is to be considered an inflammation or not, will depend on the definition and scope given to this term. In a practical point of view, the question is not one of great importance. Suffice it to say, as has been already said, that the chief anatomical characteristic is an abnormal development of the pulmonary connective tissue.

As thus characterized, chronic pneumonitis may be secondary to other pulmonary affections, more especially tuberculous disease, and it occurs as the predominant, if not a primary affection; in either case the characters which distinguish the lesion are the same. The pulmonary structure is dense, resisting, and tough. The air is expelled from the vesicles by the pressure of the extra-vesicular morbid growth; and hence is produced more or less contraction of the lung. When incised, it creaks under the knife, and the cut surfaces, instead of presenting a granular appearance, like that in the second stage of acute pneumonitis, are smooth and shining. Little or no liquid escapes after an incision. The color is more or less

dark or gray from the presence of pigment. These changes are doubtless permanent.

Circumscribed chronic pneumonitis, with the foregoing characters, is often found after death in cases of pulmonary tuberculosis. The portions of lung affected are in immediate proximity to tuberculous products or cavities. The pneumonitis leads to dilatations of bronchial tubes, which are liable to be confounded with tuberculous cavities. It occasions, at the summit of the chest, the depression which is so common in tuberculous disease. It renders the walls of cavities rigid, and is thus concerned in the causation of amphoric resonance on percussion, and amphoric respiration. It is probably, in one point of view, conservative; it forms a barrier preventing the enlargement of cavities by progressive destruction of the substance of the lung. It occurs, not only as secondary to tuberculous disease, but around cancerous nodules, extravasations of blood, and abscesses of the lungs. When secondary to these affections, it isolates and forms a barrier between the affected portions and healthy lung, preventing, perhaps, an extension of disease to the latter.

Chronic pneumonitis, as either a primary affection, or as constituting a particular disease, claims somewhat fuller consideration. It is almost always unilateral, and the whole, or the greater part, of one lung is apt to be affected. After a time, it leads to considerable, and sometimes to great contraction of the affected side, the external appearances being similar to those which often follow recovery from chronic pleuritis. The heart is dislocated by suction, as it is in certain cases of pleuritis after the absorption of the effused liquid. Pleuritic adhesions are generally found after death—another point of similarity to chronic pleuritis.

Bronchiectasis, that is, dilatation of the bronchial tubes, is frequently, but not constantly, associated. Saccular dilatations from the size of a pea to a hen's egg and more or less numerous, are found usually in connection with cylindrical dilatations. The cavities which are found, however, are not always due to bronchiectasis; they are sometimes an effect of circumscribed gangrene, and of molecular disintegration due to inflammation developed secondarily to the interstitial growth. The bronchiectasis has been attributed to the traction upon the bronchial tubes produced by the morbid growth, to the accumulation of mucus within the tubes, and to an expansion, compensative of the shrinking of the lung, caused by the dilatation of the chest in the inspiratory acts. The latter enters into the rationale, probably, more largely than the two former explanations.

The affection is of very rare occurrence. Its causation is obscure. In an exceedingly small proportion of cases, it has been preceded by acute pneumonitis; but in these cases it is perhaps most rational to regard the succession of the two affections as merely a coincidence. This may also be said of the cases in which it has been observed to follow bronchitis, in view of the fact that it is an unilateral disease, whereas bronchitis, when primary, is always bilateral; it is hardly probable that such a sequel of the latter would be limited to one lung. In short, we have no positive knowledge of its etiology. In the majority of cases, the age of patients is under forty years.

The local symptoms of this disease are cough, with more or less expectoration, and want of breath on exercise. The matter expectorated is often notably fetid, and sometimes suggestive of gangrene. Circumscribed gangrene, as already stated, occasionally occurs; but the fetor generally is due to the decomposition of muco-pus from its detention in the cavities incident to bronchiectasis. Hæmoptysis, sometimes slight, but in some

cases profuse, occurred in more than one-half of the 30 cases analyzed by Bastian.

The disease may exist for an indefinite period without notable emaciation or debility; but, sooner or later, even if there be no complication or intercurrent affection, hectic paroxysms occur, diarrhœa is not uncommon; the appetite fails, with of course a corresponding defect of nutrition. The fingers may become clubbed, as in some cases of phthisis and disease of the heart. General dropsy occurs in a considerable proportion of cases. This is due to dilatation of the right side of the heart, an effect of the obstruction of the pulmonary circulation, that is, assuming renal disease not to coexist.

The physical signs, aside from the contraction of the chest, to which reference has been already made, are dulness on percussion, rarely flatness; and the resonance which is elicited is frequently purely tympanitic. The latter is marked in proportion as bronchiectasis is a concomitant lesion; and, of course, it is most marked when the dilated bronchial tubes are free from morbid products. Saccular dilatations may occasion cracked-metal and amphoric resonance. Either ordinary cavernous or amphoric respiration may be heard on auscultation in certain situations. In other situations the respiration may be bronchial or tubular. In some situations the characters of the cavernous and bronchial respiration may be combined. On the other hand, there may be absence of respiratory sound over more or less of the affected side. The vocal signs are those denoting solidification of lung and cavities; namely, bronchophony, increased vocal resonance, and sometimes pectoriloquy. Bubbling and gurgling rales are often present. The dilatation of the right side of the heart may give rise to a tricuspid regurgitant murmur and to a jugular pulse.

As regards diagnosis, phthisis is to be excluded by the extent of the damage, taken in connection with the fact that the affection is unilateral, and with the absence of the emaciation which generally characterizes tuberculous disease. The affections with which it is most likely to be confounded, by those who take into account physical signs, are chronic pleurisy and carcinoma. Chronic pleurisy, however, after the removal of the effused liquid, does not furnish the signs of solidification, and perhaps cavities, which belong to the clinical history of this disease. Carcinoma of the lung is generally secondary to carcinomatous disease in some other situation; the cancerous cachexia is often marked; there is progressive and perhaps rapid wasting of the body, and the progress of the disease is more rapid.

Chronic pneumonitis, or cirrhosis of the lung, is irremediable, and, sooner or later, it ends fatally. But, in most cases, life is destroyed by some complication or intercurrent affection. An acute pneumonitis affecting a lobe of the sound lung, or an attack of acute bronchitis, may prove fatal. Tuberculous disease may become developed secondarily. The ability to resist any severe disease is of course impaired. Alone, the disease ends fatally by the slowly progressive exhaustion which it induces; but, existing alone, it may be borne for a great number of years.

The treatment embraces, as the most important object, maintenance of nutrition and strength. The measures for this object are remedies to improve appetite and digestion, a nutritious and abundant alimentation, climatic and other hygienic influences, which tend to invigoration. All that the physician can aim to do is to aid in rendering the system tolerant of the disease as fully and as long as possible. Palliative measures, having reference especially to cough and expectoration, are indicated, with a view to a remedial influence on the bronchial mucous membrane when the expectoration is abundant. The inhalation of the vapor of turpentine is

useful. Carbolic acid vapor or spray may be inhaled if the matter of expectoration be fetid.

Brown or Pigment Induration of the Lungs.

The lesion thus entitled and described by Virchow in 1847, is referable to the long-continued passive congestion incident to obstruction at the mitral orifice of the heart. The appearances, as described by Virchow, are as follows: The lungs do not collapse on opening the chest as when they are healthy. They are compact, heavy, inelastic, crepitating on pressure but little; and they frequently have a peculiar yellow, brown, or reddish-brown color. On section, numerous red points, dark colored at the centre and lighter at the edges, are seen, and, also, spots which are brown, rusty, or black. In the interspaces the tissue is yellow, orange, or rust-colored. The microscope shows the parenchyma to be normal, with extravasated blood in the different stages of transformation into pigment.

This lesion has been studied by Dr. Francis Delafield, one of the curators of Bellevue Hospital.[1] He found it more or less marked in 20 out of 60 cases in which there were cardiac lesions involving obstruction of the pulmonary circulation. He describes the pulmonary structure as dense and resisting pressure like compressed lung, containing but little air, and very little blood or serum escaping on section. Under the microscope four pathological conditions were observed, namely, new pigment, hypertrophy of the walls of the air-cells, dilatation of the capillaries, and a morbid increase of cellular elements within the alveoli. No extravasations of blood were observed. Dr. Delafield considers the filling of the alveoli with new cells as an important element in the lesion, although it is the one which has attracted the least attention.

The symptoms denoting the lesion are not definite, but it must increase the dyspnœa which is connected more directly with the cardiac disease.

Anthracosis, Siderosis.

The pigment in the lesion just noticed is derived from the blood. It is, therefore, of autochthonous origin. Black pigment, however, may consist of particles of coal derived from the atmosphere. The pigmentation which is more or less marked in the lungs of aged persons is measurably, thus, of external origin. The lesion caused by the inhalation of coal dust is called anthracosis. It is especially marked in the lungs of coal miners. The particles of coal, carried by the current of inspired air into the air vesicles, or alveoli, penetrate the tissues; and the microscope shows their presence in the areolar structure and in the bronchial glands. By their microscopical characters the carbon-pigment is readily distinguished from that derived from the blood; and sometimes the particles of coal are sufficiently large to be recognized by the naked eye.

Anthracosis, within certain limits, is hardly to be considered as a disease. The particles of coal may be innocuous, and, if the quantity be not large, there is no appreciable diminution of the respiratory function. On the other hand, by mechanical irritation, they may occasion interstitial pneumonitis, and, perhaps, sometimes, in circumscribed situations, suppurative inflammation of the pulmonary parenchyma. Suppuration of bronchial glands is an occasional effect, and, oftener, their destruction by atrophy.

[1] American Journal of Med. Sciences, Jan. 1871.

The term *Siderosis* denotes the accumulation in the pulmonary structures of the oxide of iron. This forms a very fine, brownish-red dust, and it is inhaled by workmen employed in dyeing, polishing mirrors, and other mechanical arts in which it is used. Accumulating in the lungs, it causes a reddish pigmentation. A German observer, Zenker, has studied its morbid effects, which are essentially the same as in anthracosis.[1]

Lobular Pneumonitis—Atelectasis—Collapse of Pulmonary Lobules.

The phrase lobular pneumonitis might, with propriety, be applied to the pulmonary affection which occurs in cases of pyæmia, and which, from embolism being involved in its causation, is also called "embolic pneumonia." This has been noticed under the heading "circumscribed pneumonitis" (page 195). The phrase, moreover, is among the several names which have, of late, been applied to tuberculous infiltration, or tuberculous pneumonitis. Aside from these applications, it has been used to distinguish an affection occurring especially in children under six years of age, but not exclusively confined to this period of life. It was described by Gerhard and Rufz, Barthez and Rilliet, and by Valleix as a form of pneumonitis peculiar to children, although, as regards the morbid appearances, presenting striking points of distinction from lobar pneumonitis. Subsequent researches by Jörg, Legendre and Bailly, and by Fuchs, tended to show that the affection is not a form of inflammation of the pulmonary parenchyma; but that the appearances supposed to denote pneumonitis are due to collapse of more or less of the lobules of the lungs. This is the pathological view most consistent with our present knowledge. The collapse of lobules is incident to bronchitis, and, hence, this so-called lobular pneumonitis is hardly entitled to be recognized as a distinct affection. Other names are broncho-pneumonia, catarrhal pneumonia, atelectasis, and apneumatosis. The two first of these are objectionable because the primary and essential condition is not an inflammation of the substance of the lungs. The significance of the two latter names will be apparent in giving some account of the anatomical characters.

The morbid appearances found after death are as follows: Solidified portions of lung, or nodules, are found, sometimes confined to one side, but almost always disseminated throughout both lungs. In general, these nodules vary in size from that of a pea to that of a filbert; but, exceptionally, a considerable portion of a lobe may be solidified. The number of nodules varies much in different cases. The situations in which they are most frequently found are the lower margins of the lower lobes, and the posterior surfaces of both the upper and lower lobes. They are generally of a dark red color, and they are abruptly defined by the interlobular boundaries. Usually the spaces on the superficies, corresponding to the nodules, are depressed; but sometimes this is not the case, and they may even project above the level of the adjacent lobules. This variation is due to a difference as regards congestion of the portions solidified. The solidified lobules are dense, resisting pressure, and sinking in water. The cut surfaces are smooth, not granular, and resemble muscle. The pleura over the solidified lobules, when these are near the superficies, retains its normal appearance; that is, there is no evidence of pleuritis. The several points of contrast will be apparent on comparing these characters with those of lobar pneumonitis (page 175). The anatomical condition is essen-

[1] Text-book of Pathological Histology, by Rindfleisch, 1872.

tially the same as that of lung condensed by pressure. From the resemblance to muscle, the term carnification is used to express this condition.

The solidified lobules in the so-called lobular pneumonitis correspond to those found in the bodies of children, dying shortly after birth, in whom complete expansion of the lungs had not taken place. In the latter cases the hard nodules are lobules which have never been inflated. They retain the fœtal state. Jörg, who described this condition in 1832, applied to it the name atelectasis, a term signifying absence of inflation. He found that by insufflation after death the solidified lobules disappeared, the air-cells being filled with air. Afterward Legendre and Bailly demonstrated that, in like manner, the solidified lobules in lobular pneumonitis could be made to disappear by insufflation; and, thus, the identity of the anatomical condition with atelectasis was established. Hence, the term atelectasis has been used to denote both congenitally solidified lobules and a return, after birth, of more or less of the lobules to a fœtal state by collapse. The term "acquired atelectasis" is sometimes used to distinguish the latter. The term apneumatosis, signifying absence of air, properly embraces solidification, both from collapse and from the persistence of the fœtal state, in other words, congenital and acquired atelectasis. This term was first used by Fuchs, in 1849, and is adopted by Graily Hewitt.[1]

Evidently the name lobular pneumonitis is incorrectly applied, if the collapse of pulmonary lobules accounts for all the morbid appearances. It appears, however, that the solidified lobules, often, if not generally, afford evidence of inflammation. This evidence consists in the presence of desquamated epithelium and leucocytes within the collapsed air-cells, without the presence of filmious exudation. Hence, the name catarrhal pneumonitis, which is used by some writers to distinguish a pneumonic inflammation without exudation, the name croupous pneumonia being used to denote inflammation with exudation. The pneumonitis, however, there is reason to believe, is secondary to the collapse. The collapsed lobules become congested, and inflammation follows. The collapse, therefore, not only occasions the gross appearances, but it gives rise to the pneumonitis when this occurs. Under these circumstances, the names collapse, acquired atelectasis and apneumatosis are more appropriate than either lobular or catarrhal pneumonitis.

For a fuller account of atelectasis and collapse of pulmonary lobules, the reader is referred to works treating of the diseases of children. The etiological relation of the latter to bronchitis will be briefly considered in the next chapter, under the heading "acute bronchitis in young children."

Collapse of pulmonary lobules will enter into the etiology of pulmonary emphysema. (*Vide* Chap. VII.)

Pleurodynia and Dorso-Intercostal Neuralgia.

A brief consideration of these affections is included in this chapter, because, from similarity as regards pain, they are liable to be confounded with either acute pneumonitis or pleuritis. Prior to the employment of physical exploration, this mistake was by no means uncommon, and it is still made by those who depend on symptoms alone. The term *pleurodynia* is applied to a painful affection of the muscles entering into the composition of the thoracic walls. *Intercostal or dorso-intercostal neuralgia* denotes a neuralgic affection of the intercostal nerves.

Both affections may be characterized by pain resembling that of either

[1] Reynolds's System of Medicine.

acute pneumonitis or pleuritis; that is, a lancinating pain felt especially in the act of inspiration. They may be accompanied by a dry cough, which is acutely painful. In cases of pleurodynia there may be febrile movement, and this may accidentally exist in cases of intercostal neuralgia. How are these affections to be discriminated from inflammation of the pleura, either primary, or occurring as a complication of inflammation of the pulmonary parenchyma?

Intercostal neuralgia, as a rule, is not accompanied by febrile movement. But this affection has a diagnostic criterion which is readily available. It consists in the existence of tenderness usually in three isolated points, viz., behind near the dorsal vertebræ; laterally in one, two, or three intercostal spaces, and anteriorly in one or more intercostal spaces near the sternum or over the epigastrium. Sometimes tenderness exists in only two of these situations. The tenderness is frequently confined to a very limited space in each situation, a space perhaps small enough to be covered by the finger. On the opposite side of the vertebræ, and between the tender points in the three situations, pressure or percussion is well borne. In addition to this diagnostic test, physical exploration fails to discover the evidence of either pleuritic or parenchymatous inflammation, viz., in primary pleuritis a friction murmur in some cases, and the signs denoting pleuritic effusion, and, in pneumonitis, the crepitant rale and the signs of solidification. The affection occurs much oftener on the left than on the right side. Both sides may be affected, but this is extremely rare.

Pleurodynia lacks a similar positive test, that is, the tenderness is not limited to isolated points, but is more or less diffused. The diagnosis, therefore, must rest on the exclusion of intercostal neuralgia by the absence of the evidence just stated, together with the absence of the signs of both pleuritis and pneumonitis. Pain in pleurodynia and intercostal neuralgia is more marked, as a rule, in movements of the body than in the respiratory movements, the reverse being true of the pain in pleuritis and pneumonitis. This remark applies more especially to pleurodynia. The tenderness in both affections varies, being sometimes slight and sometimes exquisitely acute.

Of the two affections, pleurodynia is much the less frequent. Before the diagnostic criterion of intercostal neuralgia had been pointed out by Bassereau and Valleix, cases of this affection were doubtless often considered as rheumatic, and hence, cases of the neuralgic affection have apparently increased of late at the expense of pleurodynia. Intercostal neuralgia is of frequent occurrence. Cases are numerous both in private practice and among patients treated at hospitals and dispensaries, but more especially the latter. The poorer classes are more liable to it than those in comfortable circumstances. It occurs oftener among females than males. Persons affected are frequently anæmic. It is apt to be developed during the progress of pulmonary tuberculosis. It occurs especially as a sequel of intermittent fever.

The degree of suffering from these affections varies much in different cases. They are sometimes so slight as merely to occasion annoyance, but in some cases the pain is sufficiently severe to shorten the inspirations, thus rendering the respirations frequent, as in acute pleuritis, and occasioning great distress. In the neuralgic affection, exacerbations of pain are frequently experienced. They vary greatly in different cases as regards duration, occurring sometimes as transient affections, but in some cases persisting for a long period. Pain and soreness in the chest are sometimes assumed by malingerers, but a ready proof of the reality of the affection is the diagnostic test, viz., the limitation of the tenderness to the three

points on one side of the chest. This proof is reliable, unless the malingerer have had shrewdness enough to discover that this test is relied upon for the diagnosis.

The treatment of both affections embraces measures to relieve pain if it be severe or considerable. Opium may be required internally for this object. Local applications may suffice if the pain be slight or moderate, for example, liniments containing chloroform or aconite, or the belladonna plaster. In cases of intercostal neuralgia, I have found quinia an effective remedy, whether the affection be a sequel of intermittent fever or not. The quinia should be given in doses sufficient to occasion slight cinchonism, and continued in such doses for one or two weeks. If anæmia exist, this condition claims appropriate treatment. The citrate of iron and quinia or the tincture of the chloride of iron may be prescribed with reference to this condition. In obstinate cases flying blisters are useful. Valleix considers these as most likely to prove effective. The application of dry cups will sometimes afford relief. Hypodermic injections of a solution of morphia, or of aconite, may be resorted to if the pain be severe, or morphia may be sprinkled upon a blistered surface.

Hyperæmia of Lungs, or Pulmonary Congestion.

The terms hyperæmia and congestion denote an abnormal accumulation of blood in a part, their signification being the reverse of that of anæmia as applied to any organ or structure. The congestion is of two kinds. In one, the over-accumulation is due to an abnormal determination of blood to the part affected; more blood is either sent or attracted to the part than can be readily returned by the veins from the part. This kind of congestion is distinguished as active. Virchow calls it fluxion. In this kind, arterial blood predominates in the congested part. Active hyperæmia is the first appreciable morbid condition in all acute inflammations. It constitutes a morbid condition, in certain cases, without eventuating in inflammation. In the other kind of congestion, the abnormal accumulation of blood arises from an obstruction to the return of blood from the part affected, the quantity of blood determined to the part not being increased. This is distinguished as passive congestion or stasis. Venous blood predominates in this kind of congestion.

Active congestion or hyperæmia of the lungs, irrespective of inflammation, is rarely, if ever, a primary morbid condition, and is hardly to be considered as an individual affection. It may be produced by increased power of the heart's action, arising either from transient causes, such as the ingestion of alcoholic stimulants and mental emotions, or from simple hypertrophy affecting the right ventricle, the latter being extremely rare. It may be caused by the inhalation of stimulating or irritating vapors. Whenever the circulation in a considerable portion of the lungs is interrupted, more or less abnormal determination of blood must take place in the portions to which the flow of blood is unobstructed, as in cases of emphysema, pleuritis, etc. Virchow calls this collateral fluxion.

Passive hyperæmia or congestion is of more frequent occurrence, but is never primary or idiopathic. It is an effect of mitral cardiac lesions causing obstruction or regurgitation, or both combined. It is also consequent on feebleness of the action of the heart, especially of the right ventricle, as in cases of dilatation or fatty degeneration. It is an important morbid condition as standing in a causative relation to pneumorrhagia, or pulmonary apoplexy, and to œdema of the lungs, affections to be presently considered. (*Vide* Chapter VIII.) In cases of general dropsy it occasions a dispro-

portionate and sometimes an alarming amount of hydrothorax. It gives rise to brown or pigment induration of the lungs (see p. 200).

Passive hyperæmia is liable to occur in the dependent portions of the lungs in the course of chronic diseases which occasion general debility or asthenia. The accumulation of blood, under these circumstances, is the result of gravitation, as when it takes place in the dependent portions of the lungs and of other parts of the body after death; and it may be distinguished by the name applied to the latter, to wit, *hypostatic*. Hypostatic congestion of the posterior portions of the lungs, in feeble patients confined for a long period to the recumbent posture, frequently gives rise to œdema.

Congestion of the lungs, whether active or passive, compromises the respiratory function, *first*, by diminishing the capacity of the air-cells, and, *second*, by lessening the quantity of decarbonized and oxygenized blood returned from the lungs to the systemic circulation. The respirations are increased in frequency, and a sense of the want of air, or dyspnœa, is felt, *cæteris paribus*, in proportion to the degree and extent of the congestion. As regards physical signs, congestion, if marked or considerable, undoubtedly causes a certain amount of dulness on percussion; but this is not determinable if both lungs be alike congested, or in cases in which congestion of one lung follows certain affections in the other side of the chest, as in pleurisy with effusion, pneumo-hydrothorax, etc. If the dulness on percussion be great, either œdema or extravasation of blood is superadded. Congestion also undoubtedly diminishes the intensity of the respiratory murmur; but if the murmur be changed in character, that is, if it be bronchial or broncho-vesicular, there is solidification from some cause. It is not probable that simple congestion gives rise to adventitious sounds or rales; nor does it occasion any vocal signs. Dulness on percussion on both sides, and diminished intensity of the respiratory murmur, are effects of the brown or pigment induration; but these effects may not be determinable owing to the fact that both lungs are equally affected.

The treatment must of course, have reference to the causative conditions and the circumstances under which the congestion occurs. Active congestion calls for cardiac sedatives and revulsive measures. Passive congestion is generally either hypostatic or an effect of disease of the heart. In cases of the latter, the measures are indicated by the cardiac lesions. Hypostatic congestion may be prevented or relieved by changing at intervals the position of the body, so that the same portions shall not be constantly dependent.

CHAPTER VI.

BRONCHITIS.

Acute Bronchitis affecting the Large Bronchial Tubes—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute Bronchitis. Acute Bronchitis in Young Children. Bronchitis affecting the small Bronchial Tubes. Epidemic Bronchitis. Bronchitis with Fibrinous Exudation. Circumscribed Bronchitis. Chronic Bronchitis.

THE preceding chapters have been devoted mainly to the consideration of inflammation affecting the serous covering of the lungs and the lining membrane of the pulmonary cells. It remains to consider inflammation seated in the lining membrane of the bronchial tubes. Inflammation in this situation constitutes the disease called *bronchitis*. This, in its ordinary form, is the most frequent of the pulmonary inflammations. Ordinary bronchitis is a very common affection in all parts of the globe. A highly important variety of the disease is based upon the section of the bronchial tree affected. In ordinary bronchitis, the inflammation is limited to the large bronchial tubes. An infrequent and a much graver form of bronchitis is developed when the inflammation affects the small tubes. The latter form is generally, but, as will be seen, incorrectly called *capillary bronchitis*. Inflammation of the bronchial mucous membrane may be acute, subacute, or chronic, and varieties of the disease are based on these differences as regards the degree and duration of the inflammation. Bronchitis may be primary or secondary, as regards other pulmonary affections; that is, it may be developed as a complication of certain diseases, such as pneumonitis or tuberculosis, or it may not be preceded by any disease of the lungs. As a complication of other pulmonary affections, it is more limited than when it is the primary affection, and may be distinguished as *circumscribed bronchitis*. A form of the disease is characterized by the exudation of lymph, and may be denominated *diphtheritic bronchitis*. Finally, bronchitis occurs as an epidemic, and is then commonly known as *influenza*. These several varieties of the disease will claim separate consideration, after having considered the ordinary form, viz., bronchitis affecting the large bronchial tubes. The term *catarrh* has been used to denote inflammation of a mucous structure, giving rise only to a mucous, or a mucopurulent, product. As the term bronchial cartarrh expresses neither more nor less than bronchitis, it is superfluous, and may be dispensed with. Proceeding to treat first of ordinary acute bronchitis, it will be considered as occurring after infantile life, and afterward, certain points relating to the disease as it occurs in young children will be briefly noticed.

Acute Bronchitis affecting the Large Bronchial Tubes.

ANATOMICAL CHARACTERS.—The opportunity of observing the appearances after death is not often offered, as this form of bronchitis does not in itself prove fatal. The mucous membrane differs from serous membranes and the lining membrane of the air-cells in being thicker, softer, much more vascular, and containing follicles which secrete mucus. Owing to

these points of difference, the anatomical characters of inflammation differ from those which belong to the inflammatory affections already considered. The accumulation of blood takes place in the membrane itself, whereby it is reddened and swelled. The redness and swelling after death may be found to be uniform in the affected tubes, or more marked in patches or zones. The appearance with respect to redness after death here, as in other situations, is not to be considered as evidence of the condition as regards the amount of accumulation of blood during life, for, in parts which are open to observation, for example, the conjunctiva, mouth, and throat, redness marked during life is found to diminish or even to disappear after death. The inflamed membrane is more or less softened by inflammation, and the affected tubes are likely to contain more or less of the inflammatory products which were expectorated during life, viz., mucopurulent matter, with predominance of the characters of either mucus or pus. Inflammation below the trachea very rarely leads to ulceration.

In ordinary bronchitis, the inflammation, as already stated, is limited to the large bronchial tubes. Probably in most cases it does not extend beyond the bronchi exterior to the pulmonary organs; but, in cases unusually severe, the larger divisions within the lobes may be involved. The tubes on both sides are equally affected, provided the affection be not incident to an antecedent pulmonary disease. With this exception, bronchitis exemplifies the law of parallelism; it is a bilateral or symmetrical disease. In this respect it differs from pleuritis and pneumonitis.

Clinical History.—Acute bronchitis is generally preceded by inflammation of the mucous membrane of the nasal passages, or coryza. The inflammation commences in the nostrils and travels downward, either affecting, or passing by, the pharynx and larynx in its passage to the bronchial tubes. The period occupied in the passage varies from a few hours to one, two, or three days. In a certain proportion of cases, the bronchial tubes are attacked at once without any affection of the air-passages above.

The symptoms offer marked points of contrast with acute pleuritis and pneumonitis. Pain is not a prominent symptom, but the patient experiences a sense of constriction or tightness, with a feeling of soreness or rawness. These painful sensations especially accompany acts of coughing. The pain is of an obtuse or contusive character, and is situated beneath the sternum.

The attack is rarely accompanied by a distinct chill, but chilly sensations, followed by flashes of heat, are frequently repeated during the career of the disease. The appetite may be more or less impaired, but is not usually lost. Lassitude is complained of, with a general feeling of malaise.

The febrile movement is generally moderate. The pulse has not the frequency and strength which it has in pleuritis and pneumonitis. The heat of the surface is not notably raised.

The cough is at first painful, but not sufficiently so to be suppressed. It is at first dry, the secretion of mucus being for a time scanty. Deep inspirations, breathing cold air, and the exercise of the voice in singing or speaking excite acts of coughing, which occur in paroxysms, and consist of a deep inspiration followed by a series of expiratory efforts. If the paroxysms of coughing be frequent and severe, the traction of the diaphragm occasions pain and soreness referred to the false ribs and the ensiform cartilage. The patient feels as if relief would be afforded by a more abundant expectoration, and desires to have the cough loosened. The expectoration is at first small, glairy, frothy, and viscid, and occa-

sionally streaked with blood. In the progress of the affection, after two, three, or four days, the expectoration becomes more abundant, and consists of thick, yellowish, or greenish sputa. The cough is then said to be loose, the acts of expectoration being easier, unattended by pain or soreness, and followed by a sense of comfort. The mucous secretion is rarely sufficient to accumulate in the tubes and occasion embarrassment of respiration. This may happen in young children, in the aged, and in feeble persons. The presence of a collection of mucus in the large bronchi or trachea is felt, and the patient is led to make voluntary efforts of coughing for its expulsion. The increased amount of mucous secretion and the change in character, denote diminution or resolution of the inflammation.

Respiration is not sensibly affected. No portion of the lung is withdrawn from the exercise of its function as in pleuritis and pneumonitis. Dyspnœa is not produced save in the exceptional cases in which, from feebleness or the want of voluntary efforts of coughing, the mucous secretions accumulate sufficiently to obstruct the bronchial tubes.

The affection is not accompanied by much debility. Patients are generally not confined to the bed, and they may not confine themselves to the house.

The average duration of acute bronchitis is ten or twelve days. In severe cases, after five or six days patients are usually able to be out of doors.

The disease may be divided into two stages. The first stage embraces the period during which the expectoration is scanty, transparent, and viscid. The second stage extends from the time when the expectoration becomes abundant, opaque, and thick, to convalescence.

Pathological Character.—Acute, ordinary bronchitis is an inflammation affecting a mucous structure, leading to a secretion of mucus and the production of muco-pus in greater or less abundance. Resolution takes place in this situation without the occurrence of ulcerations. It belongs among the symmetrical diseases.

Causation.—Primary or idiopathic bronchitis is supposed to be frequently, if not generally, produced by the action of cold. This is implied in the name by which the affection is popularly known, viz., "a cold." Exposure to cold is supposed to produce this disease by interrupting the eliminative functions of the skin, whereby an increased duty is thrown upon the pulmonary mucous membrane, and by inducing internal congestion. This view of the causation is inconsistent with the fact that great exposure, in a large proportion of cases, is not followed by bronchitis, and also with the fact that in a large proportion of the cases of bronchitis it is not traceable to any unusual exposure. There is abundant evidence, however, to show that exposure of a portion of the body to a current of air is liable to excite an attack of this disease. In general it is reasonable to conclude that the disease is due to a morbific agent in the atmosphere or some special atmospheric change. This is, of course, to be inferred when the disease prevails as an epidemic; but, when cases are not numerous enough to constitute an epidemic, it is a matter of common observation that a greater or less number of persons are apt to be simultaneously affected. Sometimes the occurrence of cases is connected with an obvious change in weather, but it would be useless to offer any speculations as to the particular atmospherical condition which stands in a special causative relation to the disease.

Bronchitis occurs secondarily to, and forms an element of, other diseases. It belongs to the clinical history of rubeola or measles. In this

connection it is frequently acute. It belongs to typhoid fever, but is rarely acute in connection with that disease. Developed in connection with diseases situated elsewhere than in the pulmonary organs, it is symmetrical, as when it occurs primarily; but, developed as a complication of pneumonitis and tuberculosis, it may be limited to one side, that is, unilateral, and is confined within a circumscribed space.

It may be produced traumatically by the local action of irritating gases received with the inspired breath. Inhalation of chlorine gas will produce it. I have known a severe attack produced by inhaling the fumes of sulphuric acid. In some persons, owing to an idiosyncrasy, the bronchial membrane becomes inflamed by constituents of inspired air which are innocuous when inhaled by most persons. The powder of ipecacuanha, emanations from newly-mown hay, and from feathers, certain morbific matters in the atmosphere during the summer and a portion of the autumnal season, the nature and source of which are not, as yet, ascertained, and even fragrant odors, will produce bronchitis in those constituted with a peculiar susceptibility of this membrane to be affected by these causes. Frequently, in these cases, to the bronchitis is added asthma, and this idiosyncrasy will be noticed in connection with the latter affection. (*Vide* Chap. VII.)

As a rule, the liability to bronchitis is less in proportion as persons are habituated to free exposure in the open air. It is much more apt to attack persons who spend most of their time in warm apartments than those whose occupations keep them out of doors. Soldiers, surveyors, explorers, and hunters, who are accustomed to sleep at night in tents or in the open air, rarely "take cold," but it is a matter of frequent observation that, after having been for some time accustomed to camping out of doors, bronchitis occurs on resuming comfortable in-door quarters.

DIAGNOSIS.—Acute bronchitis is to be discriminated from pleuritis and pneumonitis, more especially the latter. The points, relating to symptoms, which are involved in this differential diagnosis are as follows: The absence of lancinating pain, and the pain which is felt being sub-sternal; the presence of more or less expectoration which is not rusty, but either devoid of blood or containing it in the form of streaks; absence of accelerated breathing and dyspnœa; absence of the circumscribed flush of cheeks, the pulmonary symptoms preceded by coryza, with perhaps soreness of throat and subacute laryngitis. These points are chiefly negative, and they are not sufficient for a positive diagnosis in all cases, because the symptoms belonging to pleuritis or pneumonitis, which are wanting in bronchitis, are by no means uniformly present in cases of the two former diseases. The clinical history, however, in conjunction with the results of physical exploration, generally render the diagnosis sufficiently easy and positive.

The physical diagnosis is based chiefly on negative points. Percussion elicits the resonance of health. The vocal resonance is unaffected. The respiratory murmur may be weakened, but is not otherwise altered. Suppression of the murmur over a portion of the chest may occur temporarily from obstruction of a bronchial tube by an accumulation of mucus. These points warrant the exclusion of pleuritis and pneumonitis. The dry and moist bronchial rales may, or may not, be present at the time when the explorations are made. Their presence and diffusion, more or less, over both sides, are indicative of the existence of the disease, but the absence of the disease is by no means to be inferred because these signs happen to be wanting when the chest is examined.

Prognosis.—Acute ordinary bronchitis, not associated with other affections, is a dangerous disease only when it occurs in the young, aged, and feeble. The danger, in these classes of patients, arises from the accumulation of the products of inflammation within the bronchial tubes, and from an occasional accident which will be noticed under the head of bronchitis in young children, viz., collapse of pulmonary lobules. The danger then relates to apnœa. The disease does not lead to great prostration and danger from asthenia. Exclusive of the classes of patients just named, it is generally a disease of little or no gravity. In the great majority of cases it passes through its course and the recovery is complete, but it may eventuate in chronic bronchitis. Associated with certain other affections, it may give rise to much suffering and danger. Occurring, for example, in patients affected with pulmonary emphysema, it occasions more or less dyspnœa, and it may prove fatal if the amount of emphysema be great. So in cases of spinal paralysis affecting the costal respiratory movements, the accumulation of the bronchial secretions, from inability to expel them by the action of the diaphragm alone, may occasion death by slow apnœa. Prof Alfred Stillé has cited a case of this kind.[1]

As a rule, the disease has no tendency to induce either pleuritis or pneumonitis, and, contrary to a very general impression, it rarely precedes the development of pulmonary tuberculosis.

Treatment.—There is reason to think that acute bronchitis may be prevented, in some instances, on the appearance of coryza, by a full opiate and diaphoretic. A quarter of a grain of the sulphate of morphia, half a grain of codeia, a proportionate dose of any of the preparations of opium, or ten grains of the powder of opium and ipecacuanha, may be given for this object at bedtime, accompanied by a hot pediluvium and some warm stimulating drink, such as weak punch or toddy, or an infusion of some of the aromatic herbs, and followed in the morning by a saline purgative. If this plan of treatment do not succeed, it may mitigate the severity of the disease.

If the affection become established, it does not claim very active measures of treatment, in view of the almost uniform tendency to recovery with mere attention to hygiene. Bloodletting is not called for except in some rare cases in which the patient is plethoric, and the symptomatic febrile movement is unusually intense. Depletion by means of saline laxatives and reduced diet will generally suffice. If the attack be severe, confinement to the bed for a few days may be advisable in order to secure uniform warmth and moisture of the surface. Diaphoresis relieves the inflamed membrane, and, for this purpose, small doses of antimony or ipecacuanha may be prescribed. Patients with this disease are more comfortable when moderately perspiring. These remedies should be continued only during the first stage, that is, prior to the free secretion of mucus. In severe cases, an abundance of moisture in the apartment soothes the inflamed membrane, and renders the patient more comfortable. The Russian bath is palliative, and appears to abridge the duration of the disease.

Opium is thought by many to be contra-indicated in the first stage. It is supposed to interfere with the free secretion of mucus and render expectoration difficult. This is an inference from the effect of opium on the secretions in health; but, so far from these results being produced, opium appears to hasten the second stage. The free secretion of mucus is not

[1] *Vide* American Journal of the Medical Sciences, July, 1866, p. 146.

the cause, but the consequence, of an abatement of the inflammation; and by contributing to the latter, opium virtually acts as an expectorant. Opium, therefore, is indicated in the first stage of bronchitis, as it is in most acute inflammations. In the second stage, it is only indicated when the cough is out of proportion to the expectoration; that is, when the amount of cough existing is not needed to effect the removal of morbid products in the bronchial tubes. Opium is contra-indicated if, owing to the feebleness of the patient, the efforts of expectoration are inadequate to prevent accumulation in the bronchial tubes. The inhalation of pulverized warm water, or spray, affords relief and promotes the secretion of mucus.

During the acute stage, if pain and soreness of the chest be prominent symptoms, sinapisms or stimulating liniments are useful. These symptoms hardly claim blisters or other active measures of counter-irritation.

The stimulating so-called expectorants are not indicated in the first stage. In so far as they have the faculty of exciting the bronchial mucous membrane, they tend to increase the inflammation. They are rarely indicated in the second stage. If the affection linger and threaten to become chronic, the sulphate of quinia and other tonic remedies, together with a nutritious diet and an invigorating regimen, are the most efficient measures for recovery. I have been led by experience to regard the chlorate of potassa as a useful remedy in both the first and second stage of acute, as well as of chronic, bronchitis.

Subacute Bronchitis.

The difference, as regards symptoms and therapeutic indications, between the acute and subacute forms of bronchitis, is such that a passing notice of the latter, under a distinct head, is called for.

Subacute bronchitis is, in common language, a slight cold, beginning usually with coryza, and running the same course as acute bronchitis, but with less severity, and perhaps not involving the same extent of the bronchial mucous surface. The affection is not of sufficient gravity to keep patients within doors, and, in the majority of cases, they do not call upon the physician, but either allow it to run its course, or resort to some domestic remedies.

This form of bronchitis may frequently be rendered abortive by a full opiate at night, given in conjunction with a diaphoretic stimulant. But, if not prevented, it claims only a saline laxative, followed by a little anodyne, such as one-eighth of a grain of the sulphate of morphia every four or six hours in syrup. It is not necessary to enjoin confinement within doors. As it is desirable not to exaggerate, as well as not to depreciate, the importance of diseases, it should be understood, by physicians and patients, that common colds do not tend to eventuate in inflammation of the lungs, or in phthisis. A certain amount of care is advisable, and mild remedies are useful, but it would be injudicious to subject patients to active measures of treatment.

Acute Bronchitis in Young Children.

Acute bronchitis in young children offers an important peculiarity in the greater liability to an accident to which reference has been already made, viz., collapse of a greater or less number of pulmonary lobules, called, also, atelectasis and apneumatosis (see page 195.)

Collapse of pulmonary lobules is incidental to bronchitis in young children, in consequence of the accumulation of mucus in the bronchial tubes.

The tubes consisting of branching cylinders diminishing in calibre, it is easy to understand that plugs of viscid mucus, in certain situations, may obstruct the ingress of the inspired air into the air-cells, without obstructing the egress of air from the cells in expiration; hence, collapse occurs of the lobules to which the obstructed tubes are distributed. In expiration the plugs are moved by the current of air from the smaller into the larger tubes, but in inspiration the current moves them into a position in which the progress of air is interrupted. It is supposed that collapse may occur when the current of air in expiration as well as in the act of inspiration is obstructed, the air which is thus pent up in the lobules being absorbed. In proportion to the number of collapsed lobules, the respiratory function is compromised, and danger from apnœa may attend this accident. It is more liable to occur in young children than in adults, because children do not promote expectoration by voluntary efforts, and also because the respiratory acts are less vigorous. It occurs especially in feeble children. It does not, however, belong exclusively to acute bronchitis in young children; it occurs in aged persons, and may take place in those of any age who are constitutionally weak. It is also incidental to chronic bronchitis in children and adults, giving rise, as will be seen hereafter, to emphysema of the lungs.

The occurrence of collapse of pulmonary lobules may be strongly suspected in the course of acute bronchitis, if the respirations become frequent, with dilatation of the alæ nasi, accompanied perhaps with lividity, and if the symptoms and signs of pneumonitis be wanting. Physical exploration does not furnish definite signs of this accident. Relative dulness on percussion may be found on one side, if there be a marked disparity between the two lungs as regards the number of lobules which are collapsed. The respiratory murmur will be likely to be more feeble over the posterior than over the anterior portion of the chest, and, if relative dulness on percussion exist on one side, the murmur of respiration will be more feeble on that side. Mucous rales are more or less abundant.

In the treatment of bronchitis in young children, the liability to this accident is to be considered. Mild emetics are indicated with a view to promote the expulsion of mucus from the bronchial tubes. They are admissible because they occasion less disturbance than in adults. They are indicated because in young children the acts of coughing are for the most part purely reflex; that is, voluntary efforts to expectorate are not made. They should not, however, be repeated too frequently, and antimonial emetics should never be employed. Remedies to maintain nausea are contra-indicated on account of their depressing effect; an emetic should be given to produce prompt vomiting, and afterwards nauseant remedies withheld, until a repetition of the emetic be deemed advisable. And, in the mean time, tonic remedies, a nutritious diet, and perhaps alcoholic stimulants, are called for to support the general strength. Opium is to be given with great circumspection, since it may favor the accumulation of mucus in the bronchial tubes. The chief objects of treatment, in short, are twofold: *first*, to supply the want of voluntary efforts of expectoration by the judicious employment of emetics; and, *second*, by sustaining measures to maintain the force of the respiratory acts. The iodide of potassium, given pretty freely, has seemed to me to have a curative effect.

Acute Bronchitis Affecting the Small Bronchial Tubes.

An extension of inflammation from the larger and medium-sized tubes to those of small size, gives rise to the variety of bronchitis commonly

called capillary bronchitis. This application of the term capillary, however, is not strictly correct. The truly capillary tubes, that is, the ultimate subdivisions of the bronchial tree, or the bronchioles, are not the seat of inflammation in this affection. They are involved in pneumonitis. The bronchial branches of small size, but not the smallest, are affected in so-called capillary bronchitis. The larger tubes are generally first affected, and the small tubes become involved by a more or less rapid extension of the inflammation. The affection has but recently come to be understood, and has heretofore been known by various titles, such as catarrhus senilis, peripneumonia notha, bastard pleurisy, suffocative catarrh, etc.

This affection differs widely from ordinary acute bronchitis, as regards its clinical history and danger. It is an exceedingly grave affection, proving fatal, especially when it attacks young children, in a large majority of cases. The danger proceeds from obstruction to the current of air to and from the air-vesicles. The obstruction is incidental to the small size of the affected tubes; the swelling of the mucous membrane, and the presence of muco-purulent liquid, which, in the larger tubes, do not interrupt the free passage of air during the respiratory acts, here occasion serious interference, and, as the tubes in both lungs are affected, fatal apnœa is liable to be produced.

The anatomical characters, as regard the mucous membrane, are essentially the same as in ordinary bronchitis. The membrane is more or less reddened, swollen, and softened, and the tubes are more or less filled with muco-pus which escapes in small drops when a section of the lungs is made. The obstruction due to the contents of the tubes may lead to collapse of a greater or less number of pulmonary lobules. Portions of the lungs are apt to become œdematous. Abnormal dilatation of the air-cells of the superior and anterior portions is another effect, and, in some cases, this condition, known as emphysema, becomes developed in a great degree. Niemeyer accounts for this as follows: The forcible exertion of the respiratory muscles is brought to bear chiefly upon the lower part of the chest; the effect upon the upper portion being much less. Hence, while the air is expelled from the lower portions of the lung, it accumulates in the upper portions and thus occasions dilatation of the cells. This dilatation may be temporary, disappearing after recovery from the bronchitis. Although the inflammation reaches so near the bronchioles and air-cells, it does not tend to extend into the latter; in other words, the so-called capillary bronchitis does not eventuate in pneumonitis. Cases in which these two affections become combined, if they occur, are rare exceptions to the rule.

The mechanical obstruction, and the incidental circumstances just stated, afford an explanation of the symptoms which make up the clinical history of this variety of bronchitis; and, as regards its clinical history, it presents a striking contrast to acute bronchitis limited to the large tubes. The respirations are frequent in proportion to the severity of the case. In young children they may be increased to sixty or seventy per minute. Dyspnœa exists in a degree corresponding to the acceleration of breathing. In severe cases it amounts to orthopnœa, the patient keeping the sitting posture, and suffering extremely from the want of breath. The speech is short and jerking; the alæ nasi dilate; the face is congested and swollen, and the countenance expresses anxiety and distress. Lividity is marked in proportion to the extent to which the respiratory function is compromised. There is great restlessness. The pulse is notably frequent, but not accelerated in proportion to the respirations. Cough and expectoration are more or less prominent; the former being difficult and ineffectual from the want of breath, the latter consisting of muco-purulent matter. Nie-

meyer describes an expectoration as characteristic of this variety of bronchitis as follows: The secretion from the small tubes does not contain bubbles of air; its specific gravity is greater than that of water, and it has sufficient consistence to preserve the form of the tubes. In its passage along the large tubes it becomes mixed with mucus from the latter which contains air and consequently floats on water. The characteristic expectoration consists of mucus floating on water, with which are connected filaments sinking below the surface.

The symptoms distinguish sufficiently capillary from ordinary bronchitis, but they do not always suffice for the discrimination of this from other affections. It should never be confounded with laryngeal affections occasioning obstruction (simple or diphtheritic laryngitis), for in these affections the voice is affected, the cough is characteristic, and the respirations are labored, but not notably accelerated. Attention to the points just named will show the affection to be seated within the chest. The diseases with which it is most liable to be confounded are pneumonitis, asthma, and ordinary acute bronchitis with collapsed lobules. It may generally be discriminated from these affections by means of physical signs, taken in connection with the symptoms. The resonance on percussion is not diminished in capillary bronchitis, and it may be greater than in health, owing to an emphysematous condition of the air-vesicles. The presence of mucopurulent liquid in the small tubes gives rise to the subcrepitant rale, commingled with coarse and fine mucous or bubbling sounds. As the affection is bilateral, these moist bronchial rales, produced in the small tubes and those of larger size, are heard on both sides, and especially on the posterior aspect of the chest. The respiratory murmur is weakened. I have known the anterior, superior, and middle portions of the chest, in a young child, to become largely dilated, presenting the characteristic deformity of long-continued and great emphysema, and this appearance to disappear after recovery.

Pneumonitis is to be excluded by the absence of the symptoms and signs proper to that disease. Dulness on percussion, extending over one or more lobes, is wanting. Pneumonitis is generally abruptly developed, and is not, as a rule, preceded and accompanied by bilateral bronchitis. It is rare for pneumonitis affecting but one lobe to occasion so much disturbance of the respiration as takes place in severe cases of capillary bronchitis. The crepitant rale, if it be present, denotes pneumonitis, and, if this affection exist and have advanced far enough for the subcrepitant rale to become developed, the latter is confined to one side only, except in the rare instances in which the pneumonitis is double.

Asthma generally is accompanied with little or no febrile movement. The respirations are not rapid but labored, the labor being especially marked in expiration. They are accompanied by loud sibilant and sonorous rales. It is a paroxysmal affection, the dyspnœa not persisting as in capillary bronchitis; and, unless the case happens to be one in which asthma is experienced for the first time, the liability of the patient to this affection is known.

The discrimination from ordinary acute bronchitis with collapsed lobules is more difficult. Collapse of pulmonary lobules is incidental to capillary as well as ordinary bronchitis in young children but the extension of inflammation to the smaller tubes involves, with this contingency, a far greater amount of danger than belongs to cases in which the inflammation is limited to the larger tubes. The differential diagnosis must be based on the gravity of the symptoms, the clearness of the resonance on percussion, and the diffusion, over both sides, of the subcrepitant rale.

Pleuritis with large effusion may give rise to accelerated breathing, lividity, etc., but this affection is readily excluded by the absence of the signs denoting the accumulation of liquid in the pleural cavity.

Capillary bronchitis occurs especially in young children, and, next in frequency, in the aged, but it is occasionally met with in adults. It is always a disease of gravity, but more particularly so at the two extremes of life. In young children and the aged, it proves fatal in a very large proportion of cases. It destroys life, in some cases, very rapidly. I have known it to prove fatal in less than twelve hours after the symptoms denoted gravity of disease. The average duration in fatal cases in children is from three to five days. The duration is longer in adults, and the disease is much less grave after childhood and during middle age. In cases ending in recovery, convalescence becomes established after a duration varying from one to two weeks. Happily, it is by no means a disease of frequent occurrence even in young children. In the mode of dying, apnœa predominates; and the progress toward a fatal termination is denoted by increasing lividity, the pulse becoming more and more frequent and feeble, the skin covered with clammy perspiration, the labor and frequency of the respirations, together with cough and expectoration, diminishing toward the close of life, from muscular prostration. This variety of bronchitis sometimes, although very rarely, prevails sufficiently to be considered as an epidemic. Thrombosis, or the formation of a clot in the right side of the heart, is an occasional accident.

Treatment.—Bloodletting may be employed at the onset, under those conditions by which the employment of this remedy in other inflammatory affections is to be regulated. It is not admissible in feeble subjects, and in employing this or any other debilitating measure, the physician should not lose sight of the fact that it is important to economize the strength in order that the laborious efforts of breathing may be carried on for a length of time sufficient for the resolution of the disease. The danger and distress incident to the disease arise chiefly from the deficiency of fresh supplies of atmospheric air in the air-cells; and if bloodletting be injudiciously practised, the patient suffers from the want of both blood and air. The importance of economizing strength should also enforce circumspection in the use of saline depletants and sedative remedies. These should not be pushed to the extent of producing prostration. The difficulty consists in mechanical obstruction, which neither these nor any therapeutical measures will immediately remove. The safety of the patient depends on the maintenance of life until the disease passes through its career. The inhalation of oxygen affords marked relief of the dyspnœa. The iodide of potassium should be given freely.

Emetics in young children are advisable for a reason already stated, viz., to supply the want of voluntary efforts of expectoration. Care, however, is to be taken not to repeat them so often as to occasion exhaustion. Laxatives are useful by diminishing the contents of the intestines, and thereby giving space for the more effective action of the diaphragm in respiration. Revulsive applications to the chest are useful, but blisters are of doubtful utility.

The great object being to carry the patient safely through the disease, supporting measures are early indicated, and they are important in proportion as the symptoms denote failure of the vital powers.

Epidemic Bronchitis.

For the last four or five centuries, medical observers have noted the occurrence, from time to time, of an epidemic affection characterized by bronchitis. In most countries it is commonly known by the name *influenza*, after a term introduced by the Italian writers in the seventeenth century. In France it is called *la grippe*. As an epidemic, it is remarkable for its extensive and rapid diffusion, sometimes extending, within a brief period, over many different and widely separated countries. During its prevalence a vast number of persons of all ages are simultaneously affected. In some epidemics the fatality has been large, but, in most fatal cases, other affections are developed, more especially pneumonitis. The fatality is limited chiefly to the aged and to persons with feeble constitutions.

Influenza differs materially from ordinary acute bronchitis. The bronchial affection is not more intense, but, commencing usually with coryza, the inflammation is apt to extend to the frontal and maxillary sinuses, to the lachrymal ducts and conjunctiva, and into the Eustachian tube. Frontal headache is a prominent symptom. It is accompanied by more marked general symptoms than ordinary bronchitis, viz., chills, febrile movement, lassitude, debility, anorexia, etc. It is apt to end in free perspiration or with diarrhœa. The disturbance of the system is out of proportion to the pulmonary symptoms. It is a general rather than a local disease. The bronchitis is not idiopathic or primary, but the local expression of a constitutional affection. It is an essential fever, not merely a local inflammation with symptomatic febrile movement. It is a peculiar species of fever, running a brief career, with bronchial inflammation as its anatomical characteristic.

A special cause is involved in the production of this as of every other epidemic disease. The nature, source, and mode of action of the special cause of this, as of other epidemics, are unknown. It has been attributed to ozone in the atmosphere by Schœnbein and others, to animalculæ by Holland, and to cryptogamous productions by the late Prof. Mitchell, of Philadelphia. These different views respecting its causation rest solely on speculation. The special cause doubtless exists in the atmosphere, but it is independent of appreciable atmospheric changes. This fact was exemplified in the Massachusetts General Hospital during the extensive prevalence of this epidemic in 1832. Nearly all the patients in the hospital were affected, although the wards were kept day and night at a uniform temperature.

The disease is generally mild, but, as already stated, it is liable to lead to the development of local affections, other than bronchitis, and may in this way prove fatal. Dr. Gardiner's observations go to show that, during the prevalence of influenza, other diseases are usually severe, and the rate of mortality from all diseases is increased. The duration of an attack of influenza is from three to six days.

In the treatment of epidemic bronchitis the physician must not regard the febrile movement as symptomatic fever. This error might lead to needless depletory measures. Bloodletting is rarely, if ever, required. In healthful, vigorous subjects, brisk purging has seemed to me useful. This should not be resorted to if the patient be feeble or advanced in years. Aside from purgation, diaphoretic remedies and opium will meet the therapeutic indications. Pneumonitis, or other associated affections, will claim appropriate treatment, but debilitating or depressing measures are to be employed with greater circumspection than if the affections were primary.

In aged and feeble persons, tonic and supporting measures may be highly important.

Bronchitis with Fibrinous Exudation.

A variety of bronchitis is characterized by the exudation of coagulable lymph on the inflamed mucous surface. This characteristic feature is expressed by the names diphtheritic, pseudo-membranous, plastic, croupous or croupal, which have been applied to it. This variety of bronchitis is frequently associated with inflammation of the larynx and trachea, attended with a similar exudation, constituting the affection known commonly as true croup, and occurring also in certain cases of diphtheria. But reference is here made to bronchitis with this peculiarity, occurring independently of a similar affection of the larynx and trachea. Exclusive of the cases in which it accompanies croup and diphtheria, it is an extremely rare variety of bronchitis. The exudation is the same in character as that which takes place in the affections just named. It forms a dense, membraniform layer, which at first is closely agglutinated to the mucous surface, but sooner or later, loosened and detached by a suppurative process, is at length expectorated, if the life of the patient be sufficiently prolonged. When expectorated, the false membrane, as it is called, either has the form of patches or strips, or it is thrown off entire from portions of the bronchial tubes, and, when carefully displayed, may be found to consist of casts representing more or less of the bronchial subdivisions, presenting an appearance like boiled maccaroni. Aside from the form of cases of the tubes, the fibrinous character of the expectorated matter may be ascertained by microscopical examination and by chemical reagents. It presents the fibrillæ which characterize fibrin or lymph in other situations. Placed in a solution of acetic acid, it becomes swollen, whereas mucus contracts and is rendered more dense.

In a case reported by Dr. Stephen Rogers, of New York, casts of the bronchial tubes were repeatedly expectorated, and in a specimen presented by Dr. Rogers for the museum of the Bellevue Hospital Medical College, the size, length, and number of branches showed that they were formed in the bronchial tubes of an entire lobe, extending from the largest tubes to those of minute size. In this specimen, and in others from the same case, the casts were solid, being composed of concentric layers of fibrin. The patient finally died with symptoms and signs denoting malignant disease within the chest.[1]

The inflammation in cases of bronchitis with fibrinous exudation, is either acute, subacute, or chronic. Occurring in young children, it may occasion sufficient obstruction to compromise seriously respiration, and frequently proves fatal. Affecting adults, however, if not complicated with other grave affections, such as phthisis or pneumonitis, it rarely destroys life; and in the majority of cases the recovery is complete. I have met with a case in which it was associated with asthma and emphysema.

There are no symptoms or signs by means of which the diagnosis of this variety of bronchitis can be made out prior to the expectoration of false membrane. When this occurs, the character of the affection is, of course, manifest. This expectoration is preceded and accompanied by violent paroxysms of coughing. It is followed by a muco-purulent expectoration which may be bloody. The symptoms are relieved by the removal of the fibrinous exudations or casts. The expectoration of the latter may be re-

[1] *Vide* Trans. Med. Society of the State of New York, vol. for 1866, page 41.

peated after intervals of days, weeks, months, or even years. The character of the disease, if it prove fatal before the expectoration of false membrane takes place, may be suspected, but the symptoms and signs only show the existence of bronchitis, with obstruction of bronchial tubes, and, perhaps, collapse of pulmonary lobules.

The principles of treatment are essentially the same as in cases of acute or chronic bronchitis without this peculiar feature, and need not be separately considered. Pulverized warm water, or spray, inhaled, will aid in the separation of the false membrane.

Circumscribed Bronchitis.

As already stated, bronchitis, when circumscribed, is incidental to some other pulmonary disease. It is developed in pneumonitis, being limited to the lobe or lobes affected, and is the chief source of the expectoration in this disease if it do not go on to the suppurative stage. It occurs in pulmonary tuberculosis, and is limited to the tubes in proximity to the seat of the deposit of tubercle. The bronchitis, in this disease, furnishes the expectoration prior to the softening and discharge of the tuberculous product. The circumscribed bronchitis, in cases of tuberculosis, gives rise to physical signs of importance in diagnosis. As thus developed, bronchitis claims no special attention in a therapeutical point of view.

Chronic Bronchitis.

Subacute, persisting inflammation of the bronchial mucous membrane, constitutes chronic bronchitis. It is generally a sequel of the acute variety of the disease, but the inflammation may be subacute from the first. It is far less frequent than acute and subacute bronchitis. It occurs much oftener in aged persons than during the early and the middle period of life. In fact, exclusive of the cases in which it is associated with asthma and pulmonary emphysema, it is a rare affection prior to old age.

The anatomical characters are, redness, swelling, and softening of the membrane, these changes being either uniform within the affected tubes, or limited to irregular patches. The affected tubes are found after death to contain more or less muco-purulent matter like that expectorated during life. Contingent morbid changes are, solidified nodules caused by collapse of pulmonary lobules, dilatation of bronchial tubes and frequently dilatation of the air-cells, or emphysema, affecting especially the anterior superior portions of the lungs. The inflammation may be limited to the large, or it may extend more or less toward the small, tubes. The bronchitis associated with emphysema and asthma affects the smaller tubes, not, however, including those affected in the so-called capillary bronchitis.

The symptoms relating directly to the bronchial inflammation are essentially the same as in acute bronchitis, differing only in intensity, but connected with these symptoms, frequently, are others proceeding from associated affections.

Pain is generally wanting, or the patient complains only of a sense of uneasiness or constriction beneath the sternum. If cough be frequent and violent, soreness may be felt at the base of the chest on both sides, or at the epigastrium, due to the traction of the diaphragm on the ribs. Febrile movement is slight or wanting. A slight exacerbation of fever at night is observed in some cases. The appetite may continue good, or it may be more or less impaired. The nutrition is frequently not much, if at all, affected. The loss of weight, with the continuance of the disease,

is not marked as it usually is in cases of pulmonary tuberculosis. The patient usually does not present pallor or a notably morbid aspect.

More or less cough always exists. In frequency and severity this symptom varies much in different cases. It is paroxysmal, violent, and difficult in proportion to the small quantity and tenacity of liquid products within the affected tubes, and in proportion as the smaller tubes are involved. The expectoration also varies much in different cases. It is sometimes abundant, consisting of mucus with serous transudation. When the latter is copious, the affection has been called *bronchorrhœa*. It may consist of large, solid, greenish or ash-colored sputa, and in some cases small pearl-like masses are raised after much coughing; in cases characterized by the latter, the disease has been called, after Laennec, *dry catarrh*. The sputa may at times be streaked with blood. In general, the expectoration is muco-purulent, the purulent characters not infrequently predominating, and sometimes it appears to consist of pure pus. Formerly it was thought to be highly important to determine whether the expectoration was purulent or not, the presence of pus being supposed to denote something more than bronchitis. This is now deemed a point of comparatively little importance, since it is ascertained that pus is formed on a mucous surface. A very copious expectoration of pure pus, however, does point to some other source than bronchitis, such as the discharge of a tuberculous abscess, the third stage of pneumonitis, abscess of liver evacuating through the lung, empyema with perforation, etc. The diversified characters which belong to the expectoration in different forms of the disease are of less value, in a diagnostic view, than was formerly supposed, since the knowledge which has been acquired of physical signs furnishes a far more reliable source of information respecting intra-thoracic conditions. The obvious differential characters by which mucus and pus may be distinguished from each other are as follows: Mucus is transparent or semi-transparent; it is more or less viscid; it is stringy and not miscible with water; it retains bubbles of air and consequently floats on water. Pus is opaque, less viscid than mucus, miscible in water, and in water sinks to the bottom. These differential characters are combined in varying proportions when the matter of expectoration is muco-purulent.

Chronic bronchitis, of course, involves the same causes as the acute in the cases in which it is preceded by the latter. It may be produced and maintained by the inhalation of irritating particles of stone or metal in the exercise of certain occupations. It is supposed to be one of the varied local affections attributable to the syphilitic poison. Its continuance, in some cases, is referable to organic affections of the heart, consisting of obstructive or regurgitant mitral lesions. These act by inducing pulmonary congestion. It is an affection incidental to old age, occurring without any obvious causative agencies. It occurs in youth and middle age, irrespective of apparent causes, and is often associated with asthma and emphysema. To these affections it stands in the relation of a cause rather than an effect. In cold latitudes it is sometimes manifestly dependent on climatic causes, recurring with each successive winter, and disappearing during the summer season, or on removal to a warm climate.

It is not an affection which tends directly to destroy life. In the aged it may sometimes dispose to the development of capillary bronchitis, and thus, indirectly, prove serious. In connection with the feebleness of advanced years, it may lead to collapse of pulmonary lobules, and, in this way, shorten life. Its existence in a patient prostrated with any other disease involves danger from the accumulation of morbid products in the

bronchial tubes, which may be the immediate cause of death by apnœa. It may lead to the development of asthma and pulmonary emphysema, affections which, although not immediately dangerous, diminish the duration of life. Aside from these contingencies, the evil to be apprehended relates to the permanency of the affection. It is liable to become established, persisting for years, and, in aged persons for the remainder of life. The existence of chronic bronchitis does not involve an increased liability to the development of pulmonary tuberculosis, but, perhaps, the reverse.

The diagnosis of chronic bronchitis involves discrimination from pulmonary tuberculosis. This would be difficult, and, indeed, sometimes impossible, were the investigation to be limited to the symptoms; hence, before physical signs were studied, these two affections were of necessity confounded. The importance of making the discrimination is obvious in view of the great difference between the affections as regards prognosis. The differential diagnosis cannot be fully considered without anticipating the consideration of pulmonary tuberculosis. It will suffice to state that it is to be based mainly on the absence of the symptoms and signs which are diagnostic of the latter disease. In other words, it is concluded that pulmonary tuberculosis does not exist, from negative evidence, or reasoning by way of exclusion. The results of physical exploration, as just stated, are mainly to be relied upon, but the absence of symptoms which belong to the clinical history of tuberculosis is also to be considered, such as progressive, marked emaciation, hæmoptysis, and accelerated breathing. These symptoms are wanting in chronic bronchitis. The physical signs in this variety of bronchitis are the same as in the acute form, viz., the dry and moist bronchial rales, the resonance on percussion and the vocal resonance unaffected, the respiratory murmur weakened and sometimes suppressed over a portion of the chest from temporary obstruction of bronchial tubes.

The coexistence of pulmonary emphysema is to be determined by symptoms and signs diagnostic of this affection, which will be considered hereafter.

In the treatment of chronic bronchitis, bloodletting or other depletory measures are very rarely, if ever, indicated. The affection seldom exists under circumstances which render it desirable to lower the powers of life. Counter-irritation, by means of croton oil or stimulating liniments, is sometimes useful. The diet should be nutritious but not stimulating, consisting of milk, eggs, fowl, fish, and farinaceous articles. Meat, however, is not to be interdicted if the system be enfeebled. Wine and alcoholic stimulants are to be avoided, excepting when measures to support or strengthen the system are indicated. Attention to the surface of the body is important. In a cold or variable climate, woollen or silk garments should be worn next the skin. An undergarment of buckskin or chamois leather, worn over light woollen or silk, affords, during cold weather, great protection, and saves the inconvenience of an undue quantity of clothing. The object is to secure uniformity of the temperature of the surface, and to maintain the functions of the skin.

Medicines may be employed with a view to palliation and cure. If cough be troublesome, exceeding the amount requisite for expectoration, soothing remedies are called for. Opium, however, is to be prescribed with circumspection, in the first place, lest the habit of using it be formed: this is a consideration to be taken into account in all chronic affections; and, in the second place, in feeble subjects, and under circumstances in which there may be danger from an accumulation in the bronchial tubes, serious consequences may sometimes follow the blunting of that sense of

the presence of morbid products which leads to their removal by efforts of expectoration. Moreover, the use of opium tends to impair the digestive powers. For these reasons, other anodynes, such as hyoscyamus, conium, belladonna, and hydrocyanic acid, are generally to be preferred.

As a rule, the remedies which are given as expectorants are not indicated. The nauseant expectorants do harm by their depressing effect, and by disturbing the appetite and digestion. The stimulant expectorants, such as squill, senega, etc., are of doubtful efficacy, and, if not useful, are more or less hurtful.

Certain remedies, however, sometimes exert a curative effect. This is true of the balsam of copaiba. I have known this remedy to act almost as a specific; yet, in many cases, it has little or no effect. The iodide of potassium, also, in some cases is remarkably efficacious; but in other cases it is useless. The chlorate of potassa is sometimes a useful remedy. The muriate of ammonia is in some cases a curative remedy. I have notes of a case in which a cure was promptly effected by this remedy, the affection having existed for ten years. The bromide of potassium, or of ammonium, I have prescribed in some cases with marked benefit. Other remedies which have been found serviceable are the gum-ammoniac emulsion, arsenic in small doses not increased, naphtha, sulphur, and cubebs.

Frequently, marked benefit, as regards the bronchitis, is derived from tonic remedies in conjunction with measures to invigorate the system. The salts of quinia and the preparations of iron are often highly useful. These and other tonic remedies are indicated if the powers of the system be reduced, or the patient be anæmic. A generous diet is to be conjoined, and wine or alcoholic stimulants may be taken moderately with advantage. Out-of-door life, in such cases, should be added. This plan of treatment is applicable to a pretty large proportion of the cases of chronic bronchitis; to improve the general health, and restore vigor, are important objects in the treatment of this, as of any chronic local affection.

It is an object of treatment, in some cases, to diminish the amount of expectoration when this is excessive. For this end, astringent remedies may be prescribed, such as tannic acid, the persulphate or pernitrate of iron, and the preparations of zinc. After a bronchitis, however, has become habitual, especially in the aged, it sometimes appears to be, as it were, an element of health. At all events, patients complain of the discomfort arising from the suspension or diminution of the expectoration, and, for this reason, opiates do not procure relief. Under these circumstances, expectorants are useful as palliatives.

A late improvement in inhalations consists in the pulverization or atomization of liquids; that is, the production of spray, instead of vapor. By means of apparatus adapted to the purpose, not only is water in the form of spray brought more abundantly to the affected membrane, but medicated liquids may be employed more efficiently than when simply vaporized. The inhalation of spray medicated with various remedies has been found useful in cases of chronic bronchitis. The utility of the spray of warm water in acute bronchitis has been already referred to. In chronic inflammation the objects to be effected by the topical application of spray formed from medicated liquids are as follows:—

1. To check profuse expectoration by an astringent effect, and to modify favorably the inflamed condition of the membrane. For these objects, solutions of alum, tannin, sulphate of zinc, perchloride of iron and iodine have been found useful.

2. To promote mucous secretion and expectoration. Solutions of the

hydrochlorate of ammonia and of the chloride of sodium may be used for these objects.

3. To produce a sedative effect on the inflamed membrane, solutions of opium, conium, hyoscyamus, and cannabis indica may sometimes be employed with advantage.

4. As antiseptic as well as modifying or alterative remedies, tar and turpentine may be employed.[1]

Change of climate is sometimes advisable. A removal from a cold and variable climate to a situation in which the temperature is mild and equable may be attended with marked relief, and perhaps lead to recovery. Benefit may be looked for especially in the cases in which either immunity from the disease or marked amelioration is experienced during the summer season. The trial of change of climate is particularly advisable in the cases in which emphysema is becoming developed in connection with the bronchitis.

CHAPTER VII.

Emphysema of the Lungs. Interlobular or Interstitial Emphysema. Subpleural Emphysema. Vesicular Emphysema or Dilatation of the Air-Cells—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Asthma—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Pertussis, Whooping Cough.

IN the order of pulmonary diseases, emphysema and asthma naturally follow bronchitis, from the fact that they involve the latter disease in the great majority of cases. Emphysema, elsewhere than within the chest, denotes the presence of air in the areolar or connective tissue. It may denote the same condition as applied to the lungs. A form of emphysema of the lungs consists of the extravasation of air into the areolar tissue which unites the pulmonary lobules. This is distinguished by the name *interlobular* or *interstitial emphysema.* It arises from rupture of the air-cells, which causes a communication between the latter and the interlobular areolar tissue. The accumulation of air in this situation widens the interlobular spaces at the expense of the lobules, and thus diminishes the functional capacity of the latter. The air traversing the areolar tissue at the root of the lung may find its way into the subcutaneous areolar tissue of the neck, and become diffused over more or less of the entire body. This sometimes follows perforating wounds of the chest or injury of a lung by the extremity of a fractured rib. In cases of interlobular emphysema the air extravasated is speedily absorbed, and recovery soon takes place. There are no indications for treatment except to enjoin avoidance of muscular exertions. Another situation of the same form of emphysema is the subpleural areolar tissue. In this situation the air sometimes detaches the pleura so as to form air-blebs or tumors of greater or less size. These are not infrequently found after death. They are occasionally quite large. I have seen a pleural air-tumor as large as an English walnut. Bouillaud has reported a case in which a tumor existed

[1] *Vide* On Inhalations in the Treatment of Diseases of the Respiratory Passages, by M. Da Costa, M.D. New York Med. Journal, Sept. and Oct. 1866.

as large as the stomach. Of course, in proportion to their size, they interfere with the full expansion of the lungs, and in this way interfere with the function of respiration. They are liable to rupture during life, and pneumothorax, with or without pleuritis, may thus be produced. Cases of pneumothorax, in which recovery takes place, probably exemplify this accident, and an instance, supposed to be of this kind, has been given in a preceding chapter.

By the term emphysema, however, as applied to the pulmonary organs, is generally meant an abnormal accumulation of air within the air-vesicles. To distinguish this from the other forms just noticed, it is called *pulmonary* or *vesicular emphysema*. It has also been called *rarefaction of the lungs*. As the accumulation of air is an effect of a morbid increase of the size of the cells, the simple term *dilatation of the air-cells* expresses correctly the pathological condition. This condition is to be understood as constituting the affection under consideration.

An emphysematous condition, limited to a few lobules, is frequently incidental to the deposit of tubercle, and occurs in various pathological connections. Under such circumstances, it is not entitled to be regarded as constituting an individual disease. In the latter sense, the term emphysema denotes a greater diffusion of this condition, and, as a rule, the affection is bilateral or symmetrical. Emphysema more or less diffused is sometimes called *lobar*, and it is called *lobular* when limited to comparatively a few lobules.

Anatomical Characters.—As a rule, the lungs affected with lobar emphysema are increased in volume. They remain expanded when the chest is opened, not collapsing under atmospheric pressure, as they do in a healthy condition. Their contractility is thus impaired. They crepitate on pressure less than healthy lungs. The cells are enlarged so as to be plainly visible with the naked eye through the serous covering in the superficial lobules. They may be dried without collapsing, and, on section, frequently present spaces varying in size from a pin's head to a bean, and sometimes much larger. These are produced by rupture of the intercellular septa and coalescence of more or less of the cells. In some specimens these cavities are so numerous and large that the affected organs resemble the lungs of the batrachian reptiles. According to Dr. Gairdner, traces of collapsed lobules may generally be found on careful examination. The enlargement of volume may be sufficient to cover the heart and depress it downward and forward toward the epigastrium. The diaphragm may be flattened and depressed, pushing downward the organs situated beneath it. These changes denote emphysema existing in a great degree and extensively diffused. Existing in a less degree and not embracing all the lobules of the affected lobes, the emphysematous portions are distinguished by their prominence, dryness, and exsanguine appearance. The bronchial tubes are sometimes dilated. Evidence of coexisting bronchitis is generally present. The right side of the heart is usually dilated if the emphysema be extensive. The emphysema is rarely equal in the two lungs, and the predominance is usually on the left side. The upper lobes are much oftener affected or affected to a much greater extent than the lower lobes, and the affection is more marked in the anterior than the posterior portion of these lobes.

In some cases the emphysematous condition appears to be due chiefly to destruction of the intercellular septa from atrophy, and the volume of the lungs instead of being increased may be notably diminished. Jenner calls this "small-lunged emphysema," and the ordinary form "large-lunged

emphysema." The emphysema in these cases is peculiar to aged persons, and has been distinguished as senile emphysema. Other names are atrophous emphysema, and atrophy of lung. "Dilatation of the air-cells" is not an appropriate term as applied to this form of emphysema. The air-cells are not dilated, but the enlarged spaces are caused wholly by the coalescence of cells.

Emphysema, developed in a person free from tubercle, undoubtedly diminishes the liability to tuberculous disease. The two affections are rarely associated, exclusive of the cases in which pulmonary lobules in the vicinity of tuberculous deposits become secondarily emphysematous. In these cases the emphysema is lobular. A reason for the protection against tubercle afforded by emphysema, may perhaps be found in the diminished quantity of blood within the emphysematous portions of lung, and in the fact that the portions affected with emphysema, namely, the upper lobes, are the primary seat of tubercle in the immense majority of cases. The condition of emphysema is, also, to some extent, incompatible with hæmoptysis. Pneumonitis, as a rule, is not developed in an emphysematous patient. I have met, however, with several exceptions to this rule.

Clinical History.—Emphysema, existing to an extent to compromise considerably the respiratory function, is characterized by habitually labored breathing, and inability to take active exercise without suffering from want of breath. The laborious breathing is manifested in both respiratory acts, but especially in expiration. The rhythm of the respiratory acts is altered; the inspiration is shortened, and the expiration prolonged. As chronic bronchitis generally coexists, cough and expectoration are habitually more or less prominent as symptoms. The cough is usually violent, paroxysmal, and is characterized by a series of prolonged, spasmodic expiratory efforts, as in whooping-cough. The expectoration varies much in different cases as regards quantity and character. The acts of expectoration are difficult, and the sputa are frequently accompanied by an abundant, frothy, serous liquid, resembling soapsuds. Not infrequently sputa streaked with blood are expectorated.

The affection is chronic, and unaccompanied by febrile movement. The pulse is feeble and the body cool. Owing to an accumulation of blood within the right cavities of the heart, the surface of the body presents venous congestion, and this, together with deficient oxygenation of the blood, may give rise to a cyanotic hue. In extreme cases, lividity is marked. The paroxysms of coughing are accompanied with great congestion of the face and turgescence of the cervical veins. Symptomatic phenomena, aside from those referable to respiration and circulation, are accidental. The appetite and digestion may not be notably impaired; the body, for a considerable period, may be well nourished, but, after a time, slow, progressive emaciation takes place. The countenance has an expression of distress, which, conjoined with tumidity, and a dingy or livid hue, renders the physiognomy somewhat characteristic. At an advanced period anasarca may occur as a consequence of dilatation of the right side of the heart. Albumen in small quantity may be found in the urine, this being an effect of congestion of the kidney; and congestion of the liver and spleen may render these organs appreciably larger than in health.

These symptoms accompany the affection when it exists to an extent to compromise considerably respiration. Existing in a moderate or slight degree, there is no habitual want of breath nor labor of breathing. But the respiration is disturbed by active exercise; the patient finds himself short-winded if he attempt to run or walk fast, and this difficulty is appa-

rent, also, in speaking, singing, and especially in paroxysms of laughter. Cough and expectoration are usually present, having the same characters as when the affection exists to a greater extent, but less marked. Congestion, tumidity, and lividity are present, not habitually, but only during paroxysms of coughing or any violent physical exertion. The functions of the body generally may present little or no disturbance. Different cases exemplify all gradations between the two extremes, as regards the symptoms belonging to the affection.

Most persons affected with emphysema are subject to paroxysms of labored respiration and dyspnœa, which are due to another affection, viz., asthma. The two affections—emphysema and asthma—although so often associated, are, pathologically, distinct, and the latter will be considered under a distinct head. Acute ordinary bronchitis, occurring in a person affected with emphysema, occasions symptoms of embarrassed respiration, which do not belong to the clinical history of bronchitis occurring in a healthy person. The reason of this is to be found in the pathological character of emphysema.

The development of emphysema is generally slow. In the majority of cases, the previous history shows the commencement of the affection, as indicated by deficiency of breath on exercise, to be dated back many years, frequently extending to childhood, and not infrequently beyond the recollection of the patient. Exceptionally, it may be developed with rapidity. I have known it to occur, in a marked degree, during the progress of capillary bronchitis. The affection has no fixed duration, usually continuing, and progressively increasing, during the patient's lifetime.

Pathological Character.—Exclusive of the senile or atrophous variety, emphysema is a lesion which consists in permanent dilatation of the air-cells, with, frequently, more or less destruction of the cell-walls and coalescence of the cells. In so far as destruction of cells takes place, it is obvious that the area of the respiratory surface is diminished, and the function of respiration in this way compromised. The dilatation of the cells involves a loss of the elasticity of the lungs, so that the accumulation of air within the cells offers an obstacle to the contraction of the chest in the act of expiration. Consequently, the air in the cells is not sufficiently renewed for the purpose of respiration; the air stagnates in the cells. In this way the affection compromises the respiratory function. The distension of the cells involves pressure upon the terminal branch of the pulmonary artery, and in this way the pulmonary circulation is obstructed. This obstruction is further increased by the diminished activity of the respiratory function. The obstruction to the pulmonary circulation occasions an over-accumulation of blood in the right cavities of the heart; hence the venous congestion of the face and neck, and, to a greater or less extent, of the surface generally, with, in some cases, the phenomena of cyanosis. Hence, too, sooner or later, supervenes dilatation of the right side of the heart.

The pathological character of emphysema furnishes an explanation of the symptoms which make up the clinical history of the affection. When the respiratory function is so far compromised that the functional capacity of the lungs is insufficient while the respiratory acts are performed without effort, the want of breath is felt and the respiration becomes labored. But if the emphysematous condition be slight or moderate, no difficulty is experienced habitually, because there is still functional capacity enough for ordinary respiration. The quantity of lung in health exceeds the amount required; there is a reserve provided for any unusual demand on the respiratory function, as in muscular exercise. If, therefore, the

extent to which the respiratory function be compromised do not exceed the amount of lung held in reserve, no difficulty is experienced, save when an extra demand is made on the function. Under these circumstances, exercise, which involves an extra demand, cannot be taken without the want of breath being felt. The patient, who is habitually using the lungs to their fullest functional capacity, is disturbed by any interference with respiration. Ordinary bronchitis, which in a healthy person only requires a little of the reserved lung to be brought into play (a fact of which the patient is not conscious), occasions, if there be no lung in reserve, difficulty arising from the slight diminution of the calibre of the larger bronchial tubes which is incident to this disease; hence, patients with emphysema existing to much extent suffer from dyspnœa and labored breathing in ordinary bronchitis. The cough in connection with emphysema arises from the coexisting bronchitis; and the difficulty of expectoration is in consequence of the impaired elasticity of the lungs, the expiratory efforts in coughing not being brought to bear readily on the contents of the bronchial tubes.

The venous congestion of the face and surface generally is due to obstruction caused by over-accumulation of the right cavities of the heart. The lividity is, in a great measure, due to the same condition, but in part, perhaps, to deficient oxygenation of the blood. The smallness and weakness of the pulse also proceed from an obstruction to the free passage of the blood through the pulmonary circuit.

Causation.—The mode in which dilatation of the air-cells is produced has given rise to much discussion. Laennec, who was the first to describe distinctly this lesion, attributed it to obstruction of the bronchial tubes from the products of bronchitis. Regarding the inspiratory act as more powerful than the expiratory, he supposed air to be forced through imperfectly obstructed tubes in inspiration, and to remain imprisoned in the cells in consequence of the want of sufficient expulsive force in expiration. The dilatation, according to this theory, is produced by the rarefaction of the imprisoned air by heat, and by the reaction of the force of expiration in coughing, etc., upon the cells already filled with air. This theory is certainly not tenable in view of the fact that, of the two acts of respiration, the expiratory is a third more forcible; and still more, when voluntary and spasmodic efforts are brought to bear upon it. The more powerful the efforts of expiration, in coughing, etc., the less ought to be the liability of accumulation of air in the cells communicating with obstructed tubes. An explanation of the mode of production has been advocated by Dr. Gairdner, of Glascow, which differs essentially from the theory of Laennec. Gairdner attributes the affection to obstruction of bronchial tubes incident to bronchitis. But he supposes that the obstruction from collections or plugs of mucus leads to collapse, instead of dilatation, of the cells which communicate with the obstructed tubes, in the manner already adverted to in the chapter on bronchitis. The current of air in the act of expiration may remove the mucus from its situation, in tubes of small size, into larger tubes, where the obstruction is less; but the effect of the inspired current will be to carry it back from the larger to the smaller tubes, the mucous plugs thus acting like a ball-valve upon the orifice of a syringe; obstructing the entrance of air to the cells, but permitting the escape of air from the cells. Moreover, owing to the greater force of the expiration, the expired air may be driven past obstructions which arrest the current of air in inspiration. Collapse of more or less of the pulmonary lobules being thus produced, a larger amount of air enters the cells

communicating with unobstructed tubes, and these cells become consequently dilated. The dilatation of cells, in other words, is supplementary to the diminished volume of the lungs due to collapsed lobules, and is produced, under these circumstances, in the act of inspiration. In support of this explanation, Gairdner states that observation shows the tubes connected with emphysematous lobules to be unobstructed, and that close examination of lungs affected with emphysema will show the traces of collapsed lobules. Moreover, experiments of introducing into the air-tubes, in inferior animals, foreign bodies, such as shot and wads of paper, have been found to lead to collapse of lobules connected with the tubes in which these bodies become lodged, and dilatation of lobules connected with other tubes. This explanation will account for the production of the emphysematous lobules so frequently found in proximity to tuberculous deposits, the latter inducing, in the first place, by collapse, diminished volume of the portion of the lungs in which they are situated.

There is reason to believe that by prolonged, forcible efforts of expiration, as in long-continued exertions at lifting or pulling, or in voluntarily blowing through a partially obstructed tube, in the manner which has been to some extent practised as a means of preventing and curing consumption, the elasticity of the lungs may be diminished and permanent dilatation produced. It is well known that the chest may be in this way considerably enlarged, and deficiency of breath on exercise is sometimes a result. Expiratory efforts thus may sometimes co-operate with collapse of pulmonary lobules in the causation of emphysema. The paroxysms of whooping-cough and the labored efforts of breathing in attacks of asthma may be more or less involved in the causation.

The mechanism, as explained by Mendelssohn, and adopted by Niemeyer and others, to which reference has been already made,[1] is as follows: During violent acts of coughing the glottis is contracted and offers an obstacle to the free escape of air; and the muscles involved in the acts of coughing exert their effect especially upon the inferior portion of the chest. Under these circumstances, the air not escaping through the glottis distends the upper lobes of the lungs, and this distension, often repeated, leads to dilatation of the air-cells in these lobes. This explanation accounts for the fact of the upper lobes being especially the seat of emphysema, and that the anterior portions of the chest, in some cases, project beyond the limits of a forced inspiration in health. It is obvious that this explanation applies to the production of emphysema by forcible acts of expiration produced otherwise than in coughing. Accepting this explanation, the fact that emphysema, as a rule, is more marked in the left than in the right upper lobe, may be thus accounted for: In coughing and all forcible expiratory efforts the lower portion of the chest is more contracted on the left than on the right side, owing to the presence of the liver on the latter side.

The diminution of the elasticity of the ribs and costal cartilages, incident to advancing age, favors the production of emphysema. This change involves diminished extent and force of expiration, with undiminished, if not increased, power of inspiration. The result is, when the chest is expanded in inspiration, the lungs already contain a surplus of air. The lessened elasticity of the lungs in old persons has the same effect, keeping the organs permanently expanded.

In the production of senile, or atrophous emphysema, the point of departure appears to be atrophy and consequent rupture of the cell-walls,

[1] *Vide* chap. on Capillary Bronchitis.

leading to coalescence of more or less of the cells. The atrophous condition of the cell-walls was attributed by Rainey to fatty degeneration. Other observers, however, have failed to find sufficient evidence of this degenerative change.

Clinical observation shows that, in the great majority of cases, emphysema is not only accompanied, but preceded, by bronchitis. It can hardly, therefore, be doubted that, whatever may be the *modus operandi*, bronchitis stands, in some way or other, in a causative relation to the affection.

Emphysema is to be reckoned among the hereditary affections. This fact was first established by the late Dr. James Jackson, Jr., of Boston, who found that in 18 out of 28 cases, one or both parents had been similarly affected. Dr. Fuller found this to be true of 26 out of 43 cases.[1] An analysis of a larger number of cases with reference to this point is desirable.

The affection may be developed at any period of life. In a large proportion of cases its commencement is in infancy or childhood. Its slowly progressive increase explains the fact that patients frequently attain to middle life before the affection has advanced sufficiently to occasion great inconvenience. In a certain proportion of cases it is developed in old age, in these cases the anatomical characters consisting chiefly in destruction of the cell-walls from atrophy.

Diagnosis.—The symptoms described under the head of the clinical history are of a character to render the existence of the affection probable in the cases in which it exists sufficiently to compromise considerably the respiratory function. The probability of the existence of the affection is increased by the coexistence of asthma in a large proportion of cases. The physical signs, however, render the diagnosis positive in these cases; and in the cases in which the affection exists in a moderate or slight degree, the signs are indispensable to the diagnosis. In the latter class of cases, if asthma have not become developed, patients are often supposed to have phthisis by those who rely exclusively or mainly on the symptoms in making the diagnosis. I shall content myself here, as in treating of the diagnosis of other pulmonary affections, with giving a synopsis of the signs, referring the reader for a fuller exposition to works which treat at length of physical diagnosis.

The enlarged volume of the upper lobes of the lungs, in certain cases of emphysema, gives rise to distinctive signs obtained by inspection. In the cases in which the characters of the "emphysematous chest" are strongly marked, the diagnosis may be at once made with the eye. The upper and middle thirds of the chest, on its anterior aspect, are expanded, and present a globular or barrel-shaped form. This projection extends from the summit to the sixth rib. The obliquity of the ribs is diminished, and the angle formed by the junction of the ribs with the costal cartilages is more obtuse than in health. The inferior portion of the chest is relatively and actually contracted. The dorsal spine becomes curved anteriorly. In extreme cases, these changes amount to a deformity which is highly characteristic. The superior costal respiratory movements are lessened, and in laborious breathing the ribs and sternum are raised together, as if they formed a solid bony case. The lower anterior portion of the chest is contracted, and the soft parts above the clavicles and sternal notch are depressed in inspiration. The chest is drawn perma-

[1] Diseases of the Chest. London, 1862.

nently upward by the sterno-cleido-mastoid muscles and the scaleni, so that the neck appears to be shortened. The upper part of the chest, during the act of expiration, is in the same condition as at the end of a forced inspiration. The intercostal depressions are usually strongly marked. The heart's impulse is frequently seen and felt in the epigastrium, and is not appreciable in its normal situation.

These visible changes are present in cases in which the emphysema exists to an extent to compromise considerably the function of respiration, and in which the volume of the lungs is notably increased. The signs are more marked on the side in which the emphysema is greatest; this side being, in my experience, much oftener the left than the right. If the emphysema be comparatively slight or moderate, the size, form, and movements of the chest will not be sensibly altered. An abnormal relative fulness, however, may be observed on one side below, and perhaps above, the clavicle, with deficient superior costal movement. This disparity of the summit between the two sides, as regards size and mobility, is to be distinguished from a similar disparity due to contraction of one side from tuberculous deposit.

Percussion elicits an abnormally intense resonance, the character of the resonance being altered. The vesicular and the tympanitic quality are combined, that is, the resonance is vesiculo-tympanitic. This vesiculo-tympanitic resonance is more marked on the side corresponding to the lung which is most emphysematous. The exaggerated resonance being usually greater on one side, care must be taken not to consider the resonance diminished on the side in which it is least exaggerated. The pitch of the resonance is always higher on the side which yields the greater resonance, whereas, if the disparity be due to diminished resonance or dulness on one side, the pitch is higher on that side.

The murmur of respiration, as a rule, is weakened in proportion to the degree of the emphysema. If the affection exist to such an extent that the respiration is habitually labored, the inspiratory sound may be shortened (deferred) and the expiratory sound prolonged. The expiratory sound, however prolonged, is lower in pitch than the inspiratory, as in health. The changes in intensity and rhythm are the only modifications proper to emphysema. Not infrequently, over portions of the chest corresponding to parts of the lungs which are not highly emphysematous, the labored efforts of breathing evolve an exaggerated vesicular murmur. The weakness and alteration of rhythm are likely to be more marked on the side corresponding to the greater degree of the emphysema. Sibilant and sonorous rales, due to coexisting bronchitis or asthma, are often present in cases of emphysema.

The normal relation between the two sides, as regards vocal resonance and fremitus, continues. In some cases, owing to the displacement of the heart, the resonance on percussion within the præcordial region is abnormally clear.

In arriving at the diagnosis by means of the foregoing signs, it is to be considered that other affections, such as tuberculosis, pleuritis, pneumo-hydrothorax, are excluded by the absence of signs which should be found if these affections existed. The signs are also to be taken in connection with diagnostic points embraced in the clinical history, viz., the character of the cough and expectoration, the absence of marked emaciation, notwithstanding the duration of the pulmonary symptoms, and, in many cases, the coexistence of asthma.

In the foregoing account, reference has been had to the ordinary form of emphysema, namely, the form characterized by dilatation of the air-cells.

The atrophous form, or senile emphysema, offers certain marked points of difference, especially as regards the physical signs on inspection. The size of the chest, instead of being increased, may be notably diminished. The obliquity of the lower ribs may be much greater than in health, leaving sometimes but little space between the base of the chest and the pelvis. The resonance on percussion may be diminished.

Prognosis.—Emphysema, even in the cases in which it is most marked, rarely, if ever, involves, in itself, immediate danger. It is not a fatal affection *per se*, but it diminishes the power in the system of resisting intercurrent or superadded diseases. It leads to enlargement of the heart, which further impairs the ability to overcome other diseases. But aside from danger to life, it is an affection which, if it exist to an extent to compromise respiration, incapacitates for physical exertion, and renders life uncomfortable. Existing in a lesser degree, it is a source of much inconvenience and annoyance from the deficiency of breath on exercise.

In so far as it involves destruction of cell-walls, and the coalescence of cells, it is an irremediable lesion. And, in the majority of cases, the dilatation of the cells which takes place is permanent; the tendency, in fact, is oftener to increase rather than to decrease. I have known, however, marked improvement to take place, as shown by the physical signs. In a case in which the enlarged volume of the upper lobes was sufficient to give rise to the characteristic deformity in a marked degree, the improvement was so great that the chest nearly resumed its normal form. In so far, therefore, as the lesion consists in dilatation of the cells, it is not necessarily irremediable.

Treatment.—The treatment of emphysema has reference, first and chiefly, to the bronchitis with which it is generally associated. The object is to relieve, and, if possible, remove the bronchial inflammation which stands in a causative relation to the affection, and contributes to its increase. In proportion as the bronchitis is relieved, the condition of the patient is rendered more comfortable, notwithstanding the emphysema continues undiminished; the emphysema is less likely to increase, and it may undergo diminution.

With reference to this object, the measures to be pursued are those indicated in chronic bronchitis not connected with emphysema. The treatment, in fact, so far as this object is concerned, resolves itself into the treatment of chronic bronchitis, which has been considered in the preceding chapter. Trial should always be made of the iodide of potassium. The effect of this remedy is in some cases truly marvellous, but in other cases it produces little or no effect. It may not be amiss to remind the inexperienced practitioner that some persons cannot continue the use of this remedy, in consequence of great irritation of the fauces; and I have met with an instance in which it always produced violent vomiting and general disturbance. The eruptions on the face, to which it frequently gives rise, are an annoyance which may be submitted to, if it exert a curative effect as regards the bronchitis. When the remedy is well borne, it may be continued, in moderate doses, for a long period without any unpleasant consequences. I have known it to be continued in five grain doses, three times daily, for a year, the patient finding that, under its constant use, he was nearly free from all pulmonary symptoms. In this case the emphysema was notably lessened. The chlorate of potassa, the bromide of potassium, and the muriate of ammonia should also be tried if the iodide of potassium prove ineffectual.

Other measures, already referred to in connection with chronic bronchitis, are to be resorted to, if the remedies just named fail of success. Tonic remedies, and the regulation of diet and regimen, with a view to invigorate the system, form an important part of the treatment. If these measures fail, change of climate, if practicable, should be advised.

As there is reason to believe that violent paroxysms of cough contribute to perpetuate and increase the dilatation of the cells, palliative remedies, for this symptom, are called for, provided the bronchitis, on which it depends, cannot be removed. The labored effects of breathing in paroxysms of asthma probably have the same effect; and if this affection coexist, it is desirable, with reference to the emphysema, to relieve the paroxysms as speedily as practicable. It is important for the patient to avoid, as far as possible, attacks of acute bronchitis, and when they occur they should be cured as quickly as possible. Flatulency of the stomach or bowels and constipation contribute to dyspnœa by mechanically interfering with the play of the diaphragm. They are to be avoided by a regulated diet and appropriate remedies.

Exercise, in so far as it can be taken without inconvenience, is not to be interdicted; but exertions which induce labored breathing are to be abstained from. Prolonged efforts of expiration, as in public speaking, singing, and straining at stool, are to be avoided.

The form of emphysema distinguished as atrophous, or senile, admits of no permanent relief. Ethereal preparations and remedies to palliate dyspnœa, together with measures to support the system, comprise the treatment in these cases.

Asthma.

The term asthma has been applied, in a loose way, to dyspnœa dependent on different pathological conditions. As the name of an individual disease, it should be limited to one pathological condition, viz., obstruction of the smaller bronchial tubes from tonic spasm of the muscular fibres forming a part of the anatomical constitution of the tubes. This will exclude dyspnœa due to disease of heart, called cardiac asthma, or to any affection which does not involve spasm of the bronchial muscular fibres. Asthma and emphysema have been confounded, and, indeed, considered by some writers as one disease; but, although very often associated, they are distinct affections, and each may exist without the other. Vesicular emphysema denotes a particular pulmonary lesion, viz., either dilatation of the air-cells, or enlargement by coalescence resulting from destruction of the vesicular septa; asthma is a neuropathic affection, and does not involve necessarily any appreciable lesion. Asthma has no anatomical characters. It is true that, in the great majority of cases, pulmonary lesions are found after death, viz., those which belong to chronic bronchitis and emphysema; but this fact only shows the frequent coexistence of these affections with asthma.

Clinical History.—Asthma is essentially a paroxysmal affection. It is characterized by the occurrence of paroxysms, which recur more or less frequently, and hence it belongs in the category of diseases which exemplify the principle of periodicity. The clinical history will therefore consist of an account of the characters which distinguish asthmatic paroxysms, together with the laws of their recurrence, and the condition of health in the intervals.

A paroxysm of asthma may commence without warning, or it may be

preceded by certain premonitions. The latter are frequently experienced, provided the paroxysm be not produced by some obvious external cause. The premonitions vary in different cases. Patients who are subject to the affection are able often to predict an attack for some hours before its occurrence, sometimes by a sense of drowsiness or heaviness; sometimes, on the other hand, by an unusual excitation of the mind, and again, by sensations, the signification of which the patient has learned by experience, but which are not easily described. The paroxysm may be slowly developed, that is, an hour or two, and sometimes a longer period, may be required for its full development; or the attack may be sudden, and the intensity quickly reached. It takes place, in the great majority of cases, during the sleeping hours, and generally in the latter part of the night, or very early in the morning.

The paroxysm is characterized by laborious efforts of breathing, prompted by a painful sense of the want of air, or dyspnœa. The patient is unable to lie down, but sits with the elbows on the knees, or resting on some solid support, the head thrown backward, the mouth open and gasping with each inspiration. The respirations are not increased, but may be less in number than in health. The inspiratory act is performed with a spamodic effort, and the expiratory act is prolonged and accompanied with a wheezing sound. Speech is difficult from the want of breath, and words are uttered with interrupted efforts. Movements of the body are dreaded, and changes of position are made slowly. Cold air, from its density, affords some relief, and the patient desires the windows to be opened, without regard to chilliness of the body. The face is pallid, and sometimes presents with the palor a cyanotic hue, giving to the face a death-like appearance. Frequently, perspiration is profuse. Limpid urine, in great abundance, is passed frequently, especially at the commencement of the paroxysm. The pulse is small and feeble, due, doubtless, to an accumulation of blood in the right cavities of the heart, in consequence of obstruction to the pulmonary circulation. The surface of the body is cool or cold. The nostrils are widely dilated. The countenance denotes extreme anxiety and distress. Salter mentions a symptom which he has observed almost constantly, viz., an itching sensation under the chin, which the patient endeavors ineffectually to relieve by rubbing; and the same sensation is frequently felt on the sternum, and between the shoulders.

Paroxysms differ in severity. A patient suffering from a severe paroxysm presents a spectacle more distressing than can be well imagined; to one not familiar with the disease, he appears to be on the point of death. The suffering is considerable even when the paroxysms are so mild as not to present to the spectator a picture of great distress. Their duration differs. They may continue for a few minutes only, or for several days. Usually, after continuing for a few hours, either partial or complete relief occurs. If the relief be complete, or nearly so, tranquil sleep follows, which is peculiarly sweet and refreshing. With the diminution of suffering there is usually cough, and more or less expectoration. The expectoration is frequently small, consisting, in some cases, of a few mucous pellets, semi-transparent, and of a jelly-like consistence. Cough and expectoration, if they have not existed prior to the attack, generally continue for several days afterward, unless the paroxysm has been quite mild and brief. The expectoration is sometimes streaked with blood, and occasionally a true hemorrhage or hæmoptysis takes place.

The paroxysms recur after intervals varying greatly in duration in different cases. They recur in some cases with great regularity after a stated period, and in other cases the recurrences are extremely irregular. Some

patients suffer from a diurnal recurrence, and it is remarked by Salter that in these cases the affection is almost always associated with bronchitis or disease of the heart. Recurrence regularly after the interval of a week or a fortnight is not uncommon. Females sometimes have attacks only at the menstrual periods. Some persons experience an attack annually, and it may occur either in the winter or summer season. Examples of the latter are cases of so-called hay asthma, which will be noticed presently under another head. When the paroxysms recur irregularly, they are sometimes attributable to a particular exciting cause, but in other cases the reason of their recurrence is not apparent.

In the intervals the condition varies, the variations depending on the existence, or otherwise, of associated affections. Asthma is not infrequently associated with persisting chronic bronchitis, and, under these circumstances, more or less cough and expectoration are habitual. Emphysema is also a frequent concomitant, and deficiency of breath on exercise, or constant dyspnœa in proportion to the amount of emphysema, will characterize these cases. The habitual dyspnœa in these cases is due to the emphysema, and is not properly asthmatic. Enlargement of the heart is another affection, not infrequently coexisting, which may give rise to more or less dyspnœa.

Pathological Character.—The pathological character of asthma has been already stated in defining the term as applied to an individual disease. It is a neuropathic affection, tonic spasm of the bronchial muscular fibres being induced by a morbid excitation through the nervous system. The exciting causes of the paroxysms doubtless exert their effect through the excito-motory or reflex function of the nervous system. It is true that bronchitis generally exists at the time of the occurrence of the paroxysms, but bronchitis exists often enough without asthma; and cases occur in which the spasm takes place independently of bronchitis. In the latter cases, the affection has been distinguished as nervous asthma; but, with the pathological view just presented, asthma is always nervous, and these cases differ from the majority only in the absence of coexisting bronchial inflammation. It is probable that inflammation renders the muscular fibres more prone to spasmodic action, and, in this way, is involved in the production of the affection, but not constituting an essential part of it. The distinction between asthma and emphysema has been already sufficiently stated.

Causation.—The occurrence of asthma involves a peculiar susceptibility in the bronchial muscular fibres to take on spasmodic action. This susceptibility does not exist in all persons. It constitutes a predisposition to the affection which characterizes certain constitutions. The majority of mankind, no matter to what influences they may be exposed, never experience this affection. The predisposition may be transmitted by inheritance. Of those who become asthmatics, so large a proportion have had parents or progenitors endowed with the same peculiarity of constitution that there must be admitted to be, in some cases, an inborn and inherited predisposition. The fact of its being congenital is also shown by the occurrence of the affection not infrequently in early childhood and infancy, independently of any appreciable external causes. Whether the peculiar susceptibility be always congenital, or whether it be acquired in a certain proportion of cases, it is impossible to say. That the affection frequently does not occur until after youth, and is sometimes deferred until old age, and that it follows some other pulmonary affection, such as whooping-cough,

bronchitis, or measles (which is frequently observed), is not proof that it does not involve an innate peculiarity of constitution.

For the development of the affection, certainly in most cases, in addition to the predisposition, exciting causes are requisite. The exciting causes are various, and the facts with regard to these show, in some persons, a remarkable susceptibility to particular agencies which upon most persons produce no morbid effect. A striking illustration of an idiosyncrasy, in this regard, is the variety of the affection commonly called *hay asthma*. The emanations from newly-mown hay produce, in some persons, coryza, bronchitis, and asthma, and the latter affection may never occur save when produced by this particular cause. The term hay asthma, however, is applied to cases occurring exclusively during the summer season, although the exciting cause may not proceed from hay. We meet occasionally with persons who suffer, for a certain period during the summer months, with asthma, associated with coryza and bronchitis, and during the remainder of the year they are entirely free from the affection. Sometimes the annual visitations in successive years occur precisely on the same date, and the duration is always about the same. For example, a medical friend of the author is attacked early in September of each year with coryza and bronchitis, and subsequently paroxysms of asthma occur during the night. He continues to suffer from the former affections and the nightly recurrence of the asthma for six weeks. The affections then disappear, and, excepting for the period just stated, his health is excellent. The exciting cause is doubtless in the atmosphere, and probably proceeds from something emanating from the vegetable kingdom, but the particular agent remains to be ascertained. Perhaps, in different cases, emanations from different vegetable products are involved. In the case just referred to, relief and exemption are obtained by removing, at the period when the affections occur, to a situation devoid of, and distant from, vegetation. On going to sea, the affections are sure to disappear after sailing a certain distance from land.

The affection known as "Hay Asthma," or "Hay Fever," first described by Dr. John Bostock, in 1819, under the name *Catarrhus Æstivus*, has been studied, as it occurs in the northern part of this country, by Dr. Morrill Wyman.[1] There are two forms of annually recurring bronchial inflammation (catarrh) in persons with a peculiar idiosyncrasy. The first is often called the "rose cold," or "June cold," commencing in the latter part of May or early in June, and continuing until early in July. This corresponds with the affection known in England as "Hay Asthma" or "Hay Fever." The other form is called by Dr. Wyman *Catarrhus Autumnalis*, or Autumnal Catarrh. In this form the affection begins generally in the third or fourth week of August, and ends in the latter part of September or in October. It rarely, if ever, continues after the occurrence of black frost. Asthma occurs in a certain proportion of cases only. The local symptoms denote irritation and subacute inflammation of the nostrils and bronchial mucous membrane, together with some febrile movement, and more or less constitutional disturbance. The affection appears not to exist in the Southern States, nor in the colder regions of Canada. Dr. Wyman has collected a considerable number of cases showing that relief may be obtained by going to certain portions of the White Mountain region; also Mount Mansfield, in Vermont, one of the Green Mountains, and the Adirondac Mountains, in the State of New York.[2]

[1] Autumnal Catarrh (Hay Fever). New York, Hurd & Houghton, 1872.

[2] For further details respecting the parts of the country in which the affection occurs, and those which are exempt from it, together with its natural history, *vide* Dr. Wyman's work.

A remarkable idiosyncrasy is exemplified in the author's personal experience. This consists in the production of coryza, bronchitis, and asthma by an emanation from feather beds or pillows. I had suffered repeatedly from attacks of these affections on sleeping away from home, especially in inns and steamboats, before the source was discovered. All feather pillows and even feather beds do not furnish the special emanation, and the circumstances on which the latter depends I have not ascertained. The poisonous principle is not connected with the odor which is sometimes perceived. I cannot determine beforehand whether a strange bed will excite an attack or not. If the feathers are of the (to me) poisonous kind, shortly after retiring, labored respiration, cough, and wheezing commence, and progressively increase until I am obliged to get up, when the difficulty passes off in a few hours, leaving a little bronchitis, which continues for a day or two. I have never experienced the least degree of asthma excepting as a result of an emanation from feathers.

Dr. Richard M. Crane, of Hagerstown, Md., has communicated to me a case under his observation in which attacks of asthma were distinctly traced to sleeping beneath a feather bed made of duck feathers. The cause was not ascertained until after four years of suffering from the affection which had not existed previously, the patient being fifty years of age; and there was no return of the affection after an ordinary feather bed, made of geese-feathers, was substituted for the bed which furnished the causative emanation.

Inhalation of the powder of ipecacuanha in some persons produces similar effects. Several examples of this idiosyncrasy have been reported. On relating my own experience at a meeting of a medical society, on one occasion, a member of the society gave an account of a case in which the same effects were produced by an emanation from the body of the horse, so that the person was debarred from riding or driving on that account. I have recently heard of another case of this kind. Salter gives several examples in his work on asthma. Cases have been known in which asthmatic attacks were brought on by emanations from the bodies of other animals, as the cat, rabbit, etc.

In persons subject to asthma, the paroxysms are liable to be induced by a variety of exciting causes, but individual cases differ as regards a particular susceptibility to certain of these causes. In some cases the inhalation of dust is particularly apt to bring on an attack. I have known a patient especially susceptible to the dust of grain and that arising when carpeted rooms are swept. The fumes of burning sulphur are apt to produce asthmatic breathing in those subject to the affection. Indigestion, in some cases, proves an exciting cause oftener than anything else. Some can refer paroxysms frequently to constipation. Salter relates a case in which the application of cold to the instep was sure to provoke an attack. Mental emotions sometimes act as an exciting cause. Occasionally in females the paroxysms are habitually connected with the menstrual function.

In the great majority of the cases of asthma bronchitis coexists. In a certain proportion of cases the bronchitis is constant or habitual, and the frequency of the paroxysms depends in a measure on the bronchitis; for, if the latter affection be relieved or removed, the asthmatic attacks become less frequent. The susceptibility to the exciting causes of spasm is increased by the existence of bronchial inflammation. In other cases, the attacks of asthma occur whenever bronchitis, or a common cold, occurs. Finally, climatic influences are involved in the causation, for it is a matter of frequent observation that the same persons are much more liable to

recurrences in some situations than in others. And it is also a matter of common observation with some asthmatics residing in a locality in which they are subject to frequent recurrences, that atmospherical changes are apt to induce an attack.

Asthma occurs more frequently in males than in females, the proportion being as two to one. As regards the periods of life when it may become developed, the following are the results of an analysis of 47 cases by Dr. Salter: It was developed during the first year of life in 9, and from one to ten in 10 cases; from ten to twenty years of age in 8 cases; from twenty to thirty years in 7 cases; from thirty to forty in 6 cases; from forty to fifty in 3, and from fifty to sixty in 4 cases.

Diagnosis.—The diagnosis in well-marked cases is not difficult. The features of the asthmatic paroxysms are quite distinctive. First paroxysms occurring in young children may occasion some perplexity, but, with proper knowledge and care, the disease should not be confounded with other affections which involve embarrassment of respiration. Capillary bronchitis is distinguished by the frequency of the respirations, the acceleration of the pulse, and the diffusion over the chest of the subcrepitant rale. In asthma the respirations are not accelerated but labored, the pulse is not notably frequent, and the dry bronchial rales are abundant. Laryngeal affections involving obstruction may be excluded by the fact of the voice remaining unaffected. The dyspnœa incident to disease of the heart often goes by the name of asthma, but the breathing in this case is not labored, especially the expiratory acts, and accompanied by wheezing, as it is in asthma, and the dyspnœa is more or less habitual. Moreover, the existence of heart-lesions adequate to the production of dyspnœa is determinable by definite physical signs. Asthma and cardiac lesions, however, may be associated. If asthma have existed for some time, it is found usually associated with emphysema, and this association is diagnostic; yet, it is to be borne in mind that emphysema, sufficient to occasion dyspnœa, which may become greatly increased with a fresh occurrence of bronchitis, may exist without asthma; in other words, the dyspnœa due to emphysema and coexisting bronchitis is not properly called asthma. In addition to the abundance and diffusion of the dry bronchial rales, the physical signs, during a paroxysm, are enlargement of the chest with diminished respiratory movements, increased resonance on percussion and suppression of the respiratory murmur.

Prognosis.—A paroxysm of asthma, however severe or protracted, involves no immediate danger to life. Formidable as the affection appears, when a patient is experiencing an attack of great severity, and intense as is the suffering, it is doubtful if a fatal termination ever took place. In view, however, of the suffering incidental to the affection, and its tendency to become confirmed, with an increasing liability to recurrences, its existence must be regarded as a great calamity. If the paroxysms be produced by a particular exciting cause, which, being known, may be avoided, the disease imposes simply more or less inconvenience; but when the paroxysms are liable to be produced by various causes which cannot be guarded against, it is truly a grievous affliction; and it is calamitous, of course, in proportion to the frequency with which the paroxysms recur, and their severity.

Asthmatics are not infrequently long-lived; yet, that it may contribute to shorten the duration of life, cannot be doubted. The labored efforts of breathing in the paroxysms contribute to the development and increase of

emphysema. During the paroxysms, also, the circulation through the lungs being impeded, the right ventricle and auricle must be unduly distended with blood returned by the systemic veins, and hence the affection contributes to dilatation of the right side of the heart. The chances of long life are lessened by these lesions. Moreover, if the paroxysms be frequent and severe, they can hardly fail to impair the powers of life, and diminish the ability to resist other diseases. If asthma secure, to a certain extent, exemption from pulmonary tuberculosis and pneumonitis, this advantage is perhaps overbalanced by the fact that pneumonitis, when it does occur, is apt to prove fatal, and that the supervention of a severe attack of bronchitis is apt to destroy life.

TREATMENT.—The management of asthma embraces, *first*, the treatment of the paroxysms, and, *second*, the treatment in the intervals.

During the paroxysm the objects of treatment are to lessen the suffering and bring the paroxysm to an end as speedily as possible. The measures for these objects have reference to spasm as the essential pathological condition. The measures to relieve spasm are various, each of which proves efficacious in some cases and not in others. Frequently the past experience of the patient is the best guide as to the particular measure which will be most likely to afford relief. In cases of asthma unaccompanied by bronchitis, I have known a full opiate quickly and completely successful; but, in the larger proportion of cases, it will not succeed in cutting short the paroxysm, nor afford marked relief. Of other narcotics, stramonium is best suited to this affection. The usual mode of administration is to smoke the dried leaves or fibres of the root either in a pipe or prepared as a cigarette. It is undoubtedly true that this measure in some persons acts like a charm, and may be confidently relied upon as a prompt and effectual mode of obtaining relief; but, in the great majority of cases, it either produces no effect, or merely mitigates the severity of the paroxysm. Assafœtida, dracontium, or skunk-cabbage, and the Indian hemp have been found to be sometimes efficacious. The ethers, given internally, are to some extent useful as palliatives, and occasionally produce complete relief. Belladonna is sometimes signally efficacious, given as recommended by Salter and Ringer, namely, 10 minims of the tincture repeated every two or three hours unless disturbance of vision be produced. The bromides in full doses sometimes afford marked relief.

Marked relief is frequently obtained, and the paroxysm is sometimes cut short, by nauseant remedies, viz., antimony, ipecacuanha, lobelia inflata, and common tobacco. The two remedies last named are especially efficacious in a certain proportion of cases. The common tobacco will be more likely to be successful if the patient be not accustomed to its use. With a view to the relief of the spasm, these remedies need not be carried to the extent of producing vomiting; if not effectual when nausea is induced, it will be useless, if not injurious, to push them further. I have known a paroxysm to be arrested at once by bloodletting, but this is a measure too potent to be employed except occasionally in plethoric persons.

The inhalation of the vapor of chloroform or ether is a measure of great value in the treatment of asthma. Not infrequently the paroxysms are completely controlled by it, the patient passing, in the space of a few moments, from a condition of great suffering into one of ease and comfort. These cases are among those which afford the most striking examples of the resources of practical medicine. The dry bronchial rales which, before the inhalation, were loud and universally diffused over the chest,

sometimes disappear as soon as complete relief is procured by the inhalation, a fact proving conclusively the existence and the cessation of spasm. Unhappily this measure, like the others, is only efficacious in a certain proportion of cases. It should be tried always, provided there be no circumstances to contraindicate it. Its employment should never be intrusted to the hands of the patient. Dr. O. S. Monell, of New York, states that he has succeeded in obtaining relief in an attack of asthma by prolonging as far as practicable the expiratory act; then waiting as long as possible before inspiring, and retaining the air at the end of the inspiration as long as possible, this plan being continued for fifteen minutes. He states that he has repeatedly obtained immediate relief in this way, and that he knows of several cases in which the plan has proved successful.[1]

It is hardly necessary to say that if there be ground to suppose the attack to have been brought on by overloading the stomach or by constipation, an emetic or cathartic is indicated. And, of course, the patient is to be removed from the action of any known exciting cause, such as the emanations from hay, feathers, etc. The apartment should be large, high, and airy. Warm and stimulating pediluvia are useful as palliatives. Strong coffee, taken hot, is generally highly useful as a palliative. Another palliative measure, which sometimes proves to be curative, is to be added. This consists in diffusing throughout the apartment the fumes of burning nitre-paper, that is, bibulous paper dipped in a saturated solution of the nitrate of potassa, and dried. Some patients find great relief from this measure, and occasionally the paroxysms are arrested by it.

The treatment in the intervals has for its object prevention of the paroxysms. The removal of the predisposition would be the most effectual mode of accomplishing this object. This, however, is not to be expected, and the object is to be attained by measures having reference to circumstances which increase or act upon that susceptibility of the bronchial muscular fibres constituting the predisposition to the affection.

When, owing to a peculiar idiosyncrasy, paroxysms are excited by a particular cause, such as emanations from hay, feathers, etc., avoidance of exposure to the cause, if possible, is obviously indicated. It is doubtful if any remedy will produce insusceptibility to the action of the particular cause, or secure exemption so long as the operation of the cause continues. In the cases of summer asthma which have come under my observation, a great variety of remedies have been tried, but all without avail. The patient must either endure the continuance of the affection for several weeks, or he must seek a situation where he is not exposed to the exciting cause, whatever it may be.

In a large proportion of cases, the liability to paroxysms is more or less favored by the existence of habitual or chronic bronchitis. The relief or cure of the latter affection, in these cases, is the immediate object of treatment. The iodide of potassium should always be tried. I have known patients who were rendered comparatively comfortable, as regards the recurrences of asthma, by the use of this remedy. In small or moderate doses it may be continued indefinitely without any apparent injury. I have known from 5 to 10 grs. to be taken most of the time during four or five years, the patient finding that thereby he was protected against a recurrence of the paroxysms. The remedy will be useful in proportion to its curative effect on the bronchitis; it is, however, useful in some cases in which the coexisting bronchitis is slight, and when no apparent effect upon the latter is produced. The bromides are serviceable in certain

[1] New York Med. Record, Aug. 15, 1866.

cases, and they are well borne by some who cannot take the iodide of potassium without unpleasant effects. The chlorate of potassa is sometimes useful, and the other measures indicated in cases of chronic bronchitis may be employed. The arsenical medication, that is, arsenic in small doses continued for a considerable period, has been found in some cases highly useful.

If measures addressed to the bronchitis prove ineffectual, or if the paroxysms recur when bronchitis does not coexist, and the paroxysms be not referable to particular causes which may be avoided, nothing is to be depended on but change of locality. And it is probable that most asthmatics may find some situation in which they will be comparatively, if not entirely, free from the affection. Facts showing the immunity obtained by change of residence are remarkable, as illustrative of the apparent capriciousness of this affection. Persons residing in the country often find relief by living in cities or large towns. A change from the most salubrious part of a city to a part where the atmosphere is smoky and insalubrious as regards the general health, sometimes secures exemption from this affection. A change of apartments from one story to another, or to a different exposure, has been known to prove effectual. I have known a patient to suffer nightly from a severe attack, directly on the seashore, whereas the nights were passed comfortably a mile inland. There are no fixed laws with respect to the best climate or situation for asthmatics; each case has its own law, which is only to be ascertained by experience. In commencing trials of change of locality, a situation should be selected in which the climatic influences are the opposite of those belonging to the situation in which the patient resides; that is, if he live in the country, the city may be tried, and *vice versa;* if on the seashore, an inland situation, and *vice versa;* and so with regard to temperature, moisture, elevation, etc. The principle to be acted on is, that there is a locality in which each martyr to this complaint will suffer less, and perhaps be entirely free from it, and the plan should be to make repeated trials until the desired spot is found. I could cite from the cases which have come under my observation several in which this plan has proved successful. It is to be enjoined, wherever practicable, as soon as it is evident that other measures will not secure the patient against the suffering incident to the frequent recurrence of the affection.

Pertussis—Whooping-Cough.

This affection belongs among the diseases of children, and, for this reason, it was omitted in the first edition of this work. Although in the vast majority of cases the patients are children, it occasionally occurs after childhood and at all ages. In the cases in which it occurs after adolescence, it is important that the physician be prepared to recognize the affection. Moreover, the affection has much pathological interest. I shall, therefore, introduce a succinct account of it in the present edition of this work. The affection has no anatomical characters except those of ordinary bronchitis. Other morbid appearances found after death are due to complications which will be noticed under the head of the clinical history.

Clinical History.—The names of this affection derive their significance from certain characteristics pertaining to the cough which will presently be described. The first or the forming stage embraces a period prior to the appearance of these characteristics. The primary symptoms are those of simple coryza and bronchitis. Frequently during this period there is

nothing which denotes the affection to be other than a common cold. But, in the majority of cases, the cough is more violent than in an attack of ordinary bronchitis; the acts of coughing persist for a longer time, and they progressively increase in duration and violence. There is also more or less febrile movement, which is more marked and continues longer than in ordinary bronchitis. At length the cough becomes distinctly, and in a marked degree, paroxysmal, and the distinctive features of the affection relate especially to the paroxysms. The duration of this first stage varies from two to three days to two to three weeks. After the affection has advanced to the second stage, the patient is generally aware for a few moments previous to a paroxysm that it is impending. A child engaged in play suddenly is quiet, and the countenance expresses apprehension and distress. The morbid sensations are a sense of constriction, and an irritation in the larynx and trachea. These premonitions are sufficient to arouse the patient when asleep. The paroxysm is denoted by cough which is characterized by a series of violent expiratory acts succeeding each other so quickly that the patient is unable to take an inspiration between them. The number of expiratory coughing efforts which thus follow without an inspiration, varies, according to the severity of the paroxysm, from six to twenty. A long and labored inspiration then takes place, giving rise to a crowing sound evidently due to spasm of the glottis; this is the whoop which enters into the name of the affection. Another series of coughing expiratory acts succeeds, followed again by the sonorous inspiration or whoop; and these alternate acts of coughing and whooping are repeated until the paroxysm ends. The contraction of the lungs by the spasmodic acts of coughing interrupts not only inspiration, but the pulmonary circulation, so that an accumulation of blood takes place in the right cavities of the heart. These effects are shown by notable congestion and lividity of the face and turgescence of the cervical veins. Tears flow in abundance. The suffering from dyspnœa is in proportion to the violence and length of the paroxysm. The contents of the stomach are frequently expelled; and, at the close of the paroxysm, more or less mucous secretion is expectorated. In proportion to the violence and length of the paroxysm the patient is fatigued or exhausted. However severe the paroxysm, there is scarcely any immediate danger either from apnœa or syncope. I have never known of an instance of death in a paroxysm. A medical friend, however, has related to me a case in which the breath was lost, and restored by resorting to the procedure known as Marshall Hall's ready method.

The paroxysms, in different cases, differ widely in severity, duration, the degree in which the characteristics are marked, and in frequency of recurrence. When extremely severe, they occasion great distress, and serious incidental events are liable to occur which will be presently noticed. On the other hand, when quite mild they are comparatively trivial. Only one or two of the spasmodic expiratory acts may occur, or they may be repeated so that the paroxysm lasts for several minutes. The whoop is more or less loud and long in proportion to the amount of spasm of the glottis. Although generally present and marked, being, as the name implies, the most characteristic feature of the paroxysm, it is sometimes slight and sometimes wanting. In the latter case, the character of the disease has to be determined by other diagnostic features. A few paroxysms only may occur in the twenty-fours hours, or they may recur during night and day at short intervals. They may amount to even a hundred within the twenty-four hours. In almost all cases they occur in greater number in the night than during the daytime, and in some cases they occur

only at night. Exceptionally they are more frequent during the daytime. The paroxysms which occur in sleep are, of course, not produced by any obvious exciting cause. This is also true of paroxysms occurring in the waking hours. Physical exertion and mental excitement, especially the latter, appear not unfrequently to determine the occurrence of a paroxysm. Children are apt to experience a paroxysm whenever a fit of crying takes place. A patient is apt to have a paroxysm on witnessing a paroxysm in another patient, this fact illustrating the power of involuntary imitation.

Various events are incidental to the paroxysms, especially when the latter are severe. One of the most frequent of the incidental events is hemorrhage. Epistaxes is the most common form of hemorrhage. Not infrequently blood flows from the nostrils, in more or less abundance, with every paroxysm; and the loss of blood inducing notable anæmia, this favors the persistence of the hemorrhage. Hæmoptysis is an occasional form of hemorrhage. Blood sometimes escapes from the conjuctiva, or accumulates beneath this membrane. Trousseau cites a case in which a nævus situated on the face was the seat of hemorrhage with each paroxysm. Blood has been known to be forced from the ears. The primary and chief cause of the hemorrhage is the venous congestion arising from accumulation of blood within the right cavities of the heart. The urine and fæces, or both, are sometimes expelled involuntarily during the paroxysm. Intestinal hernia is sometimes produced. Rupture of air-vesicles is an accident which sometimes occurs, giving rise to interlobular emphysema; and the air, finding its way along the areolar tissue connected with the primary bronchi and trachea, may produce emphysema of the neck and even extend over the entire body. Dilatation of the air-cells, or vesicular emphysema, is another incidental event. It is questionable whether this be not due to the bronchitis associated with whooping-cough rather than to the violent acts of coughing; but the latter, at all events, contribute to its production. When the paroxysms recur frequently, and are generally accompanied by vomiting, the system suffers from innutrition. Here is a source of anæmia in addition to the hemorrhages. Convulsions occur in some cases, especially in children, being attributable to the cerebral congestion occasioned by the venous obstruction of the right side of the heart.

In the intervals between the paroxysms, aside from complications or intercurrent affections, the general condition will depend on the frequency of the paroxysms, their severity, and the incidental events. The patient is enfeebled in proportion as the paroxysms are long, violent, and frequent, and in proportion to the amount of hemorrhage, and the interference with nutrition by vomiting. The face is pallid in proportion to the anæmia. The veins of the neck furnish the venous hum, and the arteries a bellows murmur. Cephalalgia is a prominent symptom in some cases, arising from cerebral congestion. The febrile movement, which generally exists, in a greater or less degree, during the first or forming stage, as a rule, disappears when the characteristic paroxysms are established, that is, in the second stage. If it continue into this stage, or if it be reproduced, it is due to an unusual intensity of the bronchitis, or to some inflammatory complication. The face is swollen or puffed, and this, with the pallor, renders the appearance quite characteristic. Certain complications are liable to occur, which add much to the gravity of the affection. Mild bronchitis is a part of the affection. It is almost invariably present.

If the affection be uncomplicated, physical exploration of the chest elicits good resonance on percussion, with, perhaps, the dry or moist bronchial rales. The bronchitis in some cases is unusually acute, giving

rise to febrile movement and abundant mucous secretions. Collapse of pulmonary lobules is liable to occur in young children. The occurrence of vesicular emphysema (probably dependent on collapse of lobules) has been already stated. The inflammation may extend into the minute bronchial tubes, giving rise to capillary bronchitis. This will be denoted by the subcrepitant rale diffused over the chest, in conjunction with great frequency of the respirations, notable acceleration of the pulse and lividity, the resonance of the chest on percussion not being diminished. Pneumonitis is developed in some cases. Pleuritis with effusion is another complication, which is more likely to occur in adults than in children. These several pulmonary complications are rendered severe and dangerous by the recurrence of the paroxysms of whooping-cough. Frequently the latter become less violent and frequent when any of the complications just named are developed; so that a premature improvement as regards the paroxysms of whooping-cough may be an unfavorable omen. When whooping-cough is accidentally associated with some acute disease, such as measles or scarlet-fever, the paroxysms of cough, as a rule, become less frequent and violent; these intercurrent diseases interfere with the natural course of the affection. Finally, whooping-cough appears to determine the development of phthisis in some cases in which the tuberculous diathesis exists.

The duration of the affection is subject to considerable variation. Exceptionally the affection ends, of its own accord, in a few days. These cases are infrequent; but the fact that the affection is occasionally of short duration, when let alone, is to be borne in mind with reference to the supposed efficacy of remedies in abridging or arresting it. It is rare for the affection to end within a period of six weeks. In the majority of cases it continues for a longer period than this, and it sometimes persists for many months. As a rule, it gradually declines before it disappears, the paroxysms by degrees becoming less frequent and severe. Frequently, for a considerable period after the affection has ended, the characteristics are manifested, to a greater or less extent, whenever a bronchitis or common cold is contracted, or cough is excited by any cause. Trousseau states that the affection continues for a long or short period in proportion to the duration of the symptoms prior to the characteristic paroxysms; that is, if the latter are delayed the affection will be protracted, but if they are quickly developed the affection is not likely to last long.

Pathological Character.—This remarkable affection consists of three pathological elements. Bronchitis is one of these. This is the initial element. It is stated that this element is sometimes wanting, but examples must be exceedingly rare. Another element is fever. This is more or less marked in different cases, but is seldom wanting during the first or forming stage. The fever, as a rule, is out of proportion to the bronchitis, and is, therefore, to be regarded as not symptomatic, but idiopathic or essential. The most prominent of the three elements relates to the nervous system. This is manifested by the spasmodic expiratory movements in the paroxysms of cough, and by spasm of the glottis, giving rise to the whoop. Some have considered the affection as belonging among the neuroses, others have considered it to be an essential fever, and by others it has been considered as a peculiar variety of bronchitis. It is neither of these separately, but collectively they constitute the affection. Dependent, as will be seen presently, on a special cause, the primary, essential pathological condition is general or constitutional, of which the bronchitis and cough are the local expressions.

Causation.—Whooping-cough is an infectious disease; that is, it is communicated by a miasm generated in the bodies of those affected with it. It probably originates in no other way. It is highly infectious, and the number of those who pass through childhood without contracting it are few. Young infants are liable to contract it. No period of life is exempt from susceptibility to the infectious miasm. The reason for the infrequency of the affection after childhood is, the great majority of persons experience it before adolescence. Having been once experienced, the susceptibility thereafter ceases. This is the rule, but exceptionally the affection is experienced more than once. The exceptions to the rule as applied to this affection are not more numerous than to the rule as applied to other affections in the same category, for example, the eruptive fevers. The average period of incubation is not well ascertained. It is variable, the limits being one and two weeks.

Diagnosis.—When whooping-cough has advanced beyond the first or forming stage, and the characteristics pertaining to the paroxysms are well marked, it is recognized without difficulty. Its diagnostic features are sufficiently evident to those non-medical persons who have seen cases of it. The whoop is a diagnostic criterion, but this is sometimes imperfect, and even wanting. In these cases the diagnosis is to be based on the occurrence of paroxysms presenting the characters of well-marked whooping-cough, *minus* the whoop, on the duration of the affection, and on the fact of known exposure to infection, together with knowledge of the fact that the patient has not already experienced the affection. The affection may be so mild and short that there is considerable doubt whether it has really occurred; but such cases are very rare. It is desirable to make a probable diagnosis during the first or forming stage; that is, before the disease is fully declared by the characteristic paroxysms. It should be strongly suspected when cough and febrile movement are out of proportion to the bronchitis, and continue unduly. Of course, the prevalence of the affection and known exposure are to be taken into account. There is no known method of preventing the disease, other than by isolation as regards exposure.

Prognosis.—Whooping-cough is rarely fatal *per se;* yet, indirectly, it leads to a considerable loss of life. Occurring in the course of other diseases—for example, measles, or during the ailments incident to dentition—it is apt to prove a serious affection. A fatal result is generally due to complications, the more frequent and important of which have been stated, viz., capillary bronchitis, pleuritis, pneumonitis, vesicular and interlobular emphysema, and phthisis. Young children, especially during dentition, are sometimes carried off by convulsions. As regards the affection itself, the gravity and danger are proportionate to the frequency and severity of the paroxysms, the duration of the affection, the degree of anæmia and innutrition induced by hemorrhage and vomiting.

Treatment.—The treatment of whooping-cough embraces curative and palliative measures. It must be admitted that there are no known means by which the affection may be arrested; that is, abortive means. Measures are curative if they abridge the duration of the affection, or diminish notably its severity, and there are various remedies which possess more or less curative power.

Emetics were formerly considered as curative, given every other day for the space of a week or longer, at the commencement of the affection.

They were much extolled by Laennec, who preferred, as the emetic drug, ipecacuanha. Others have preferred the sulphate of zinc. Trousseau advocates, instead of the zinc or ipecacuanha, the sulphate of copper, given in solution, in small doses, according to the age of the patient, the doses being repeated at short intervals until vomiting is produced. In view of the testimony in behalf of the treatment with emetics, its efficacy in some cases cannot be doubted; but, owing to its severity, it is nearly or quite obsolete in this country. This method of treatment, it is to be borne in mind, is not admissible except early in the career of the affection.

Of other curative remedies, some are addressed to the bronchitis, and others to the neuropathic element. A combination of cochineal and the carbonate of potassa, commonly known as the cochineal mixture, has been much employed in this country; this mixture consists of cochineal, half a scruple; of carbonate of potassa, a scruple; of white sugar, a drachm, in four ounces of water. A dessert-spoonful is to be given three times daily to a child a year old, and the dose increased in proportion as the age is greater. The affection is undoubtedly in some cases favorably modified by this preparation, as shown by diminution of the violence of the paroxysms, and of the frequency of their recurrence; these effects of remedies can generally be appreciated when the affection has not already continued sufficiently long to attribute the improvement to a spontaneous decline. It is not so easy to appreciate the fact of the duration being abridged, as the natural duration varies within wide limits. This remedy probably acts upon the bronchitis. Meigs considers the cochineal as inert, and states that he has found the same benefit from the carbonate of potassa alone, dissolved in syrup of gum and water.[1]

Alum, which was recommended highly by Golding Bird, is considered by Meigs as giving more decided and satisfactory results than any other remedy which he has employed. From one to six grains may be given every four hours, the dose being graduated to the age. Dissolved in some form of syrup and water, it is not an unpleasant remedy. This remedy probably exerts its curative effect by acting upon the bronchitis.

Belladonna has been recommended as a valuable curative remedy by many physicians in different countries. Trousseau lays down certain rules with regard to its administration, which he deems essential in order to secure its curative efficacy. The dose at first should be quite small—one-tenth of a grain for a child a year old, and one-fifth of a grain for a patient four years, or more, of age. The quantity to be taken in the twenty-four hours is to be given in a single dose. The dose is to be gradually increased until its effect upon the severity or frequency of the paroxysms is apparent. It should then be continued steadily without further increase. The action of this remedy is doubtless upon the neuropathic element of the affection. Some have regarded conium, stramonium, and hyoscyamus as not inferior to belladonna in this affection. In some remarks on the treatment of certain functional and organic affections of the nervous system, before the American Medical Association, in May, 1866, Brown-Séquard states that whooping-cough may be cured in three days by giving atropia in doses large enough to produce delirium, and continued so as to keep up that condition for three days, except at night, when the patient is to be quieted by morphia or codeia. Brown-Séquard adds that it will be hard to get the consent of the parents to this method of treatment if they are told beforehand how the medicine will act. The method is precisely the opposite of that pursued by Trousseau. Brown-

[1] A Practical Treatise on Diseases of Children. By J. Forsyth Meigs, M.D.

Séquard claims that his method arrests the neuropathic symptoms, but the bronchitis remains for some time after the treatment is discontinued.

Strong testimony has been borne by not a few physicians to the curative efficacy of nitric acid. Dr. Arnoldi, of Montreal, claims for this remedy much power in abridging the duration of the affection, as well as in diminishing its severity. His mode of administration is as follows: To a tumblerful of well sweetened water the acid is to be added until the acidity is of the strength of pure lemon-juice; of this a dessert-spoonful is to be given to a child a year old every hour, and a larger quantity above that age.

Since the bromides were introduced into medical practice, they have been employed considerably in this affection, and with apparent benefit. These remedies are probably useful as pharyngeal and laryngeal anæsthetics; hence, they are addressed to the neuropathic element of the affection.

Other remedies which have been recommended, and which I shall simply name, are, tannic acid, assafœtida, arsenic, quinia, chloroform, the oxide of zinc and ergot. A measure which seems to claim something more than to be merely named was recently brought before the French Academy of Medicine, viz., inhalation of the fumes disengaged in the purification of coal-gas. It having been observed that children living in the vicinity of gas works suffered but little from whooping-cough, and recovered after a short career of the affection, the effects were tried upon a large scale, and, as stated by Commerege and Bertholles, in their reports to the French Academy, with signal benefit to a large proportion. To secure the advantage of this measure, patients should inhale the fumes at the place where the gas is purified, for the space of two hours at a time, for twelve consecutive days.[1] It would appear from the statements by Blache, Barthez, and Roger that this measure is often inefficacious. I have known of a single case in which it appeared to be promptly curative.

Of the different remedies which have been noticed, all are doubtless more or less curative in a certain proportion of cases. It may be doubted if any of them ever have a specific effect. They are, severally, useful in some, and not in other cases; the degree of the usefulness of each varies in different cases, and, with our present knowledge, the physician cannot judge beforehand what particular remedy in any individual case will be most useful. Under these circumstances, if those first selected prove inefficacious, others are to be successively tried.

Palliative treatment is important. Relief may be afforded by opiates in small doses, if they be well borne, by ethers and the hydrocyanic acid. Strong coffee has been found to be sometimes useful as a palliative.

Hygienic measures form an important part of the treatment. If there be no complications which interfere with exposure to the open air, this should by all means be advised and enforced. Under proper prudential restrictions, the more out-of-door life the better. The diet should be nutritious. If, from the frequency of vomiting, the system suffer from innutrition, alimentation becomes an important object of treatment. The patient should take food often, and as soon after a paroxysm as possible. The times for giving food should be chosen as far as practicable remote from the paroxysms, and eating at the most favorable times should be insisted upon despite the absence of appetite. Solid is to be preferred to liquid food, as less likely to be rejected by vomiting. Trousseau states that in some cases patients vomit with the paroxysms which occur in the

[1] *Vide* American Journal of the Medical Sciences, No. for April, 1865.

daytime, and not with those occurring during the night; and in such cases food should be taken freely during the night. The stomach is sometimes made to tolerate food by minute doses of opium. Change of air is sometimes of signal efficacy in modifying the severity of the affection and bringing it to a close.

Hemorrhages, if profuse or recurring frequently, claim hæmostatic measures of treatment.

Complications call for the therapeutical measures appropriate under other circumstances, making due allowance for the effects of this affection on the circulation, the blood, nutrition, and the general strength of the system.

CHAPTER VIII.

Pulmonary Hemorrhage. Bronchorrhagia. Pneumorrhagia. Pulmonary Gangrene. Pulmonary Œdema. Carcinoma within the Chest. Hydatids.

PULMONARY hemorrhage occurs under the following different circumstances: *First*, and most frequently, the hemorrhage is into the bronchial tubes, giving rise to the spitting of blood, or *hæmoptysis*. Adopting the suffix expressive of hemorrhage, with the name of the anatomical situation, this variety of pulmonary hemorrhage should be called *Bronchorrhagia*. *Second*, it occurs from the rupture or ulceration of bands of pulmonary substance which traverse tuberculous excavations, these bands sometimes containing vessels of sufficient size to occasion a copious hemorrhage. It is then an accident occurring in the course of pulmonary tuberculosis, and gives rise almost invariably, if not always, to hæmoptysis. *Third*, the blood is contained within the air-cells, and may escape into the interstitial areolar tissue, and coagulation takes place in these situations: that is, the blood is extravasated, constituting what is commonly called pulmonary apoplexy, and usually under these circumstances there is hæmoptysis. The latter form of pulmonary hemorrhage may be distinguished as *pneumorrhagia*. In the second of these three varieties, the hemorrhage is so uniformly and plainly incidental to one affection, viz., pulmonary tuberculosis, that it will suffice to simply refer to it here. Bronchorrhagia and Pneumorrhagia, however, not being so constantly symptomatic, each of a particular affection, and sometimes occurring when the pathological connection of the hemorrhage is not obvious, claim some consideration independently of the affections in which they are liable to occur.

Bronchorrhagia, or bronchial hemorrhage, exists in the great majority of the cases in which hæmoptysis occurs. The latter term should be limited to the spitting of blood; and it should be applied only to the cases in which pure or unmixed blood is expectorated. It is not properly applicable to the sputa streaked with blood which belong to the history of bronchitis, nor to the blood intimately mixed with mucus in the rusty expectoration of pneumonitis. A true hæmoptysis is the raising of blood, and blood only. In bronchorrhagia the bronchial mucous membrane is the seat of the hemorrhage. A solution of continuity is probably requi-

site, as in all hemorrhages wherever seated. In the rare cases, however, in which the loss of blood has occasioned death, ulcerations have not been found on post-mortem examination; the hemorrhage is of the kind called capillary, the orifices through which the blood escapes being too minute to be discoverable with the naked eye.

It is important to determine, when blood is ejected from the mouth, whether it come from the air-passages. It may come from the stomach, from the posterior nares, and from the mouth or fauces. If it come from the stomach, it is ejected by acts of vomiting; it is likely to be commingled with other contents of the stomach; it has the characteristic acid odor of the latter, and gives an acid reaction, whereas pure blood is alkaline. Coming from the stomach, it usually has a black grumous appearance due to the action of the gastric acids. If it come from the posterior nares, it is in the form of dark solid sputa, which are removed by acts of hawking. If it come from the mouth or fauces, the fact may generally be ascertained by a close inspection of these parts. When it comes from the air-passages, it is raised by acts of coughing, which are generally not violent; the blood rises into the trachea and larynx, and is expelled with slight efforts. In the majority of cases, the blood is liquid, of a bright arterial hue, and contains air-bubbles in more or less abundance. If, however, the hemorrhage have taken place slowly into the bronchial tubes, and remained there for some time before being expectorated, it undergoes coagulation, and acquires a dark or almost black appearance.

The amount of hæmoptysis varies much in different cases. It is sometimes quite small, a drachm or so of blood only being raised; usually, however, when the amount is relatively small or moderate, several drachms or a few ounces are expectorated. Not infrequently the amount is considerable. It is not rare for patients to lose, during an attack of hæmoptysis, from half a pint to a pint of blood, and sometimes a much larger quantity. The blood is expectorated with more or less rapidity. The continuous duration of an attack of hæmoptysis may vary from a few minutes to several hours and even many days; in the latter case, of course, the blood escaping slowly. Occasionally the flow of blood is so rapid that it escapes simultaneously from the nose and mouth; and death by suffocation may result from the accumulation in the air-passages. A single attack only may occur, or attacks may be repeated at intervals varying greatly in duration in different cases. In some cases attacks recur daily, or repeatedly during the day, for a variable period. In other cases the attacks recur after days, weeks, months, or years. After an attack it is common for the expectoration to be more or less colored with hæmatin for several days. In proportion as it is rapidly discharged it is less frothy than when the quantity expectorated with each act of coughing is small. When the hæmoptysis is rapid and abundant, if the patient be not in advanced phthisis, the bursting of an aneurism should be suspected. It is to be borne in mind that this is a source of hæmoptysis, an aneurismal tumor sometimes opening into a bronchus or the trachea. The hemorrhage from this source, however, is not always at first abundant and rapid, the opening being, for a time, too small for the free escape of blood. In cases of phthisis advanced to the cavernous stage, the hæmoptysis may be rapid and abundant, leading sometimes to fatal syncope, the hemorrhage being due to the opening of a vessel contained in one of the bands of pulmonary tissue which frequently traverse tuberculous cavities.

In the majority of cases, bronchial hemorrhage is, in some way, pathologically connected with pulmonary tuberculosis, and, from the frequency of this connection, it is important as a diagnostic symptom of that disease.

Not infrequently it is the first event which awakens the attention of patients to the existence of pulmonary disease. In a large proportion of cases, it occurs more or less frequently during the progress of tuberculosis. In a certain proportion of cases it precedes the deposit of tubercle; or, at all events, it occurs when coexisting physical signs do not afford evidence of a tuberculous deposit, these signs becoming developed, sooner or later, after its occurrence. Hæmoptysis should always excite a strong suspicion of either existing or impending tuberculous disease; yet, its significance in this respect was undoubtedly over-estimated by Louis in his treatise on phthisis. Louis, having questioned a large number of patients affected with various diseases other than tuberculosis, and finding that spitting of blood had taken place in no instance save after injury of the chest or when the catamenia were suppressed, concluded that this symptom is almost pathognomonic of tuberculosis. Since the publication of that work, however, it has been found that cases are not very infrequent in which hæmoptysis is not accompanied nor followed by either the symptoms or signs of tuberculous disease. My own clinical records furnish a considerable number of such cases. But a paper communicated by the late Prof. John Ware contains statistical information of special value with reference to this point.[1] Prof. Ware, in this paper, gave the results of an analysis of 386 cases of hæmoptysis, noted in private practice during a period of about forty years. Of these cases, in 62 recovery from the bronchial hemorrhage took place, and the patients afterward were either known to be living in ordinary health, or to have died of other diseases having no connection with the existence of tubercles. The length of time during which this immunity continued varied from two to thirty-seven years. In addition to these cases, in 52 a similar complete recovery took place, and, so far as known, there was no development of tuberculous disease, but the entire subsequent history of these cases had not been obtained. Making allowance for the probable occurrence of a small deposit of tubercle which underwent arrest and did not return, in a certain proportion of the cases, these facts show that neither the existence of tuberculosis nor a strong proclivity thereto is to be positively predicated on the occurrence of bronchorrhagia. They show, moreover, that, as regards any immediate or remote evils, bronchial hemorrhage may be quite innocuous.

Bronchorrhagia is incidental to certain cardiac lesions, especially those involving obstruction at the mitral orifice. These lesions lead to bronchial hemorrhage by inducing pulmonary congestion. It may occur in connection with morbid conditions of the blood and tissues, which lead to hemorrhages from the mucous membrane in different situations, as in purpura hemorrhagica and scorbutus. It occurs occasionally in asthma. It may be produced by violent and prolonged muscular exertions, without the coexistence of any pulmonary or cardiac affection, and it has been observed to occur from muscular exertions, not excessive, if conjoined with diminished pressure of the atmosphere in elevated situations, as in ascending high mountains. It may be produced traumatically by injuries and wounds of the chest. It may occur as a secondary hemorrhage when the menses are suppressed. Well authenticated cases of this kind have been reported, but they must be exceedingly rare. I have met with a striking example, the hæmoptysis occurring regularly for the four years following the suspension of the menses, and no other pulmonary affection either accompanying or following the hemorrhage. The 386 cases analyzed by

[1] On Hæmoptysis as a Symptom, by John Ware, M.D., etc. Publications of the Massachusetts Medical Society, 1860.

Prof. Ware did not include a single case in which the hemorrhage could be considered as supplementary to the menses. Exertion and mental excitement, by their effect on the circulation, may act as exciting causes, if, from pulmonary disease or other circumstances, a predisposition exists; but clinical observation shows that, in the larger proportion of cases, the hemorrhage takes place without any other exciting cause. It takes place frequently during the night-time.

The occurrence of hæmoptysis generally occasions much alarm and anxiety. If patients are seen at the time, the nervous agitation and disturbance of the circulation, which are often present, are attributable, in a great measure, if not altogether, to the mental condition induced by the attack. The first duty of the physician is to endeavor to dispossess the mind of needless apprehensions. Hæmoptysis, proceeding from bronchial hemorrhage, may destroy life, either by suffocation or by exhaustion from the loss of blood; but the cases are so very rare that the danger of fatal consequences is scarcely to be considered. The physician may assure the patient of the absence of any immediate danger. Nor, in general, does the hemorrhage lead to any evil results. It is suggestive of the existence of a grave affection, especially tubercle, but, aside from its symptomatic significance, it affords little occasion for alarm. So far from favoring a tendency to tuberculous disease, there is ground for the suspicion that it sometimes takes the place of a tuberculous deposit. And when it occurs in connection with tuberculosis, clinical observation shows that it exerts no unfavorable influence on the progress of that disease, but, on the contrary, its influence seems, as a rule, to be favorable.

In exceptional cases, bronchial hemorrhage apparently leads to either the development or an increase of pulmonary symptoms, together with more or less fever; and the immediate local and constitutional sequences are sometimes exceedingly grave. I have met with a case in which a young man, apparently in good health, was seized with hæmoptysis while making an evening visit at the house of a friend. The hemorrhage was profuse, and it was not considered prudent for him to return home. When I saw him, a few days afterward, he had a very frequent pulse, great frequency of respirations with dyspnœa, a high temperature, and extreme prostration. Death took place within a fortnight from the date of the attack. I have met with several cases in which, dating from an hæmoptysis, the same symptoms occurred in a lesser degree, the cases ending fatally after a certain number of weeks or months. Such cases, however, are rare. Niemeyer attributes these symptoms to the retention of coagula in the bronchial tubes, and the inflammation which their presence excites. He states that he has verified this by the post-mortem appearances. In the striking instance just cited, which came under my observation, an autopsical examination was not practicable. According to Niemeyer, in many cases, after an attack of hæmoptysis, close observation shows some elevation of temperature, with frequency of the pulse, and, not infrequently, the signs of circumscribed pneumonitis and pleuritis are discoverable. These evidences of local and general disturbance, in general, disappear within a short time. In cases of death directly following a profuse hemorrhage, the bronchial tubes have been found, post-mortem, filled with clots; and the obstruction of respiration caused by these, doubtless, was the immediate cause of death. Blood-casts of the bronchial tubes are sometimes expectorated.

The measures of treatment directed to the hæmoptysis must have reference to the profuseness, or otherwise, of the hemorrhage and the associated symptoms. Venesection, heretofore, has been frequently employed. This,

however, is indicated only in cases in which the patient is plethoric, or the pulse is abnormally strong, and such cases are comparatively few. Even in these cases, unless the escape of blood be unusually rapid and abundant, a saline purgative and sedative remedies are to be preferred to bloodletting. If the hemorrhage be profuse and persisting, it has been proposed to apply cold to the chest, as in hemorrhages in other situations. This may be done by means of compresses wet with iced water, or with ether which refrigerates by its rapid evaporation. Even the application of ice to the chest has been recommended, and I have resorted to this mode with apparent success, and without any untoward consequences. Revulsive measures may be employed, consisting of stimulating pediluvia, sinapisms, and dry cupping. To diminish the amount of blood returned to the heart, temporary ligation of the extremities may be resorted to. I have witnessed a prompt arrest of the hemorrhage by this measure. A popular remedy is common salt, which usually has been freely given before patients come under the care of the practitioner. Its efficacy is doubtful, but its use serves to occupy the attention of the patient and friends until medical advice be obtained.

In all cases, quietude of body is to be enjoined, the use of the voice is to be restrained, the apartment should be kept cool, the head and shoulders should be raised, the diet should be bland or unstimulating, drinks should be cold, and small pieces of ice may frequently be taken into the mouth. These measures are, doubtless, of more or less importance, yet I have repeatedly known patients who, having become accustomed to attacks of hæmoptysis, paid little or no attention to it, and kept about their ordinary pursuits, as usual, without apparently increasing or protracting the hemorrhage by this course. I have known a lecturer continue the daily use of the voice in public speaking, without any apparent injury. The measures just enumerated are apt to be continued too long, patients being anxious to prevent a recurrence of the hemorrhage after it had ceased. They may be assured that moderate exercise out of doors, a nutritious diet, etc., will not be likely to reproduce an attack.

Cough, if present, should be quieted by some form of anodyne. Anodyne remedies are also generally indicated by the excited condition of the nervous system. If the hemorrhage be slight or moderate, as a rule, nothing is required in addition to these remedies and such hygienic regulations as may be deemed prudent. If, however, the hemorrhage be considerable and prolonged, astringent remedies may be employed. Of the vegetable astringents, krameria and tannic or gallic acid may be mentioned as the most efficient. Ergot appears to be a valuable hemostatic in this as in other hemorrhages. Of the astringents belonging to the mineral kingdom, the acetate of lead has long been considered valuable in this application. The most efficient preparations of this class, however, are the persulphate and pernitrate of iron. The inhalation of astringent remedies in the form of atomized liquids or spray has been found effective for the arrest of hemorrhage. For this purpose solutions of alum, tannin, and the perchloride of iron may be employed.

I have met with a few cases of persistent bronchial hemorrhage which claim a separate notice. The hemorrhage, in these cases, was slight, but it continued for a long period, without other evidence of pulmonary disease. It was not referable to disease of the heart, to suppression of the menses, or to any appreciable cause. Moreover, the hemorrhage was confined to the bronchial mucous membrane; and the blood did not come from either the mouth, throat, or hard passages. The hemorrhagic expectoration was not pure blood, but a thin, bloody liquid. I have notes

of three cases. In two of these cases, after expectorating almost daily more or less of a sero-sanguinolent liquid during several months, recovery took place under the use of tonics and invigorating hygienic measures. In the third case, the hemorrhagic expectoration has continued for six years, during which period it has from time to time come under my observation. The patient is a young woman, and repeated examinations of the chest by others, as well as myself, have failed to discover any positive signs of pulmonary disease. During the greater part of the long period just named, there has been daily more or less expectoration of liquid containing hæmatin, the quantity being always small. Associated with this symptom are anæmia and hysterical ailments. Aside from these, nothing is discoverable.

Pneumorrhagia, or extravasation of blood into the air-cells, and in certain cases, also, infiltration of the interstitial tissue, is commonly known as pulmonary apoplexy. There would be no impropriety in this use of the term apoplexy if we adopted the custom heretofore of French writers of expressing by it extravasation of blood into any situation, and nothing more; but with us, when applied to a cerebral affection, it includes cases in which there is no extravasation of blood, and it is not customary to apply it to extravasations elsewhere than in the brain and lungs. The continued use of the term, as applied to pulmonary extravasation, is therefore objectionable, and, agreeably to the nomenclature now in vogue, pneumorrhagia expresses the morbid condition.

Pulmonary extravasation is sometimes incidental to bronchial hemorrhage, the blood being forced backward from the bronchial tubes into the air-cells by violent acts of inspiration. To this variety of pneumorrhagia, Laennec applied the term hemoptoic infarctus. Watson relates a case in which this took place from ulceration of the lingual artery, blood passing into the larynx, and being drawn thence into the air-cells. It has been known to take place in cases of suicide by cutting the throat. It therefore probably sometimes happens in cases of bronchial hemorrhage when associated with affections giving rise to spasmodic inspirations, or when the flow of blood is so rapid and abundant as to be with difficulty expectorated. This, however, is not an adequate explanation of all cases of pulmonary extravasation. In the cases in which the extravasated blood occupies a considerable or large area, and when it is contained in the interlobular spaces as well as in the air-cells, the primary situation is probably within the latter, the hemorrhage being from the terminal branches of the pulmonary artery or the radicles of the pulmonary veins, whereas in bronchial hemorrhage the blood comes from the venous or arterial ramifications connected with the bronchial artery.

The morbid appearances in fatal cases of pneumorrhagia are of two kinds. In one form, solid masses or nodules, varying in size from that of a pea to an English walnut, and more or less numerous, are found in either one lung or in both lungs. On section they present a dark or even black color, and grumous blood can be scraped from the cut surfaces. The solidification is due to blood coagulated within the cells. The limits of the nodules are sharply defined by the lobular divisions, and the nodules feel like hard tumors, which project above the level of the pleural surface if they be situated near the superficies; they are, however, oftener seated in the centre of the lobe than near the surface, and they are oftener found in the lower than in the upper lobes. In the other form, the extravasation gives rise to, or is connected with, laceration of pulmonary tissue, and there is a wider diffusion of the coagulated blood. In this form, larger

portions are solidified by the coagulated blood and they are not bounded by the lobular divisions. The blood is contained in the areolar tissue as well as in the cells. There is sometimes considerable breaking down of the pulmonary tissues, forming spaces which are filled chiefly with coagula. Rupture of the pleura has been known to occur, followed by a discharge of blood into the pleural sac, and giving rise to pleuritis. The two forms of extravasation may be distinguished as circumscribed and diffused. The latter is the more serious, and, as already stated, probably the hemorrhage takes place within the cells, the source being the vessels connected with the pulmonary artery. Gangrene may occur as a result of either of the two forms of extravasation.

The disseminated nodules first described as characterizing circumscribed pneumorrhagia, are identical with those which have been already noticed as occurring in certain cases of pulmonary embolism. (*Vide* page 78.) The name hemorrhagic infarctus is applied to them by late writers. Pulmonary embolism, thus, may be the immediate occasion of circumscribed pneumorrhagia, as, also, of circumscribed gangrene of lung. The question then arises whether embolism be not the cause of hemorrhagic extravasation in all cases, exclusive of those in which the hemorrhage is diffused, with laceration of tissue, and, also, of those in which blood is inhaled from the bronchial tubes into the air-cells. Accepting the current doctrine of embolism and hemorrhagic infarctus, it is consistent therewith to answer the foregoing question in the affirmative. Doing so requires a modification of the rationale, heretofore accepted, with respect to the etiological relation of disseminated extravasations to disease of the heart. This form of pneumorrhagia and disease of the heart are associated often enough to show a causative relation of the former to the latter. The explanation which has heretofore seemed adequate is that certain cardiac lesions, namely, those giving rise to mitral obstruction, cause disseminated extravasations by inducing pulmonary congestion. It seems, however, more rational to consider that mitral obstructive lesions are causative by favoring the occurrence of thrombosis in the right side of the heart. This is liable to occur when as a consequence of mitral lesions the right ventricle becomes weakened by dilatation; and thrombi here may furnish emboli, which give rise to hemorrhagic infarctus in disseminated circumscribed portions of the lungs. This explanation, however, of course, does not apply to the hemorrhagic infiltration of air-cells which results from bronchorrhagia, Lænnec's hemoptoic infarctus; nor is it applicable to hemorrhagic infiltration of the areolar tissue, or diffuse pneumorrhagia. The latter may sometimes, although very rarely, be produced by violent contusions of the chest. In general, it is an effect of distension of the pulmonary vessels, that is, passive congestion incident to mitral obstructive lesions. It is intelligible that, under these circumstances, the giving way of the vascular coats will be favored by atheromatous or other changes which diminish their resistance to the mechanical pressure produced by the distension from an over-accumulation of blood, and, also, by causes which, aside from the cardiac lesions, promote pulmonary congestion.

The diagnosis of either form of pneumorrhagia is, by no means, always easy.

Hæmoptysis is, of course, present when the source of the hemorrhage is bronchial, and the extravasation is due to the inhalation of blood into the cells. This symptom is also present in the majority of cases in which the hemorrhage takes place within the cells, but it may be wanting. When present, the hæmoptysis may be either small or abundant; the

amount of extravasation is by no means in proportion to the quantity of blood expectorated. The respirations are hurried and labored in proportion to the extent of lung solidified by the extravasated blood. Dyspnœa and a sense of oppression are also proportionate to the degree in which the respiratory function is compromised. These symptoms, however, are measurably due to the coexisting cardiac lesions when the latter stand in a causative relation to the hemorrhage. Dulness on percussion will be found over a space, or over spaces, corresponding to the situation and extent of solidification. This may not be appreciable if the extravasation be in the form of small disseminated nodules. But if the extravasation be diffused over a considerable space, the dulness becomes a very significant sign, provided tuberculosis, pneumonitis, and other affections involving solidification can be excluded. A feeble bronchial respiration may be associated with the dulness on percussion, or the respiratory sound may be suppressed over the extravasation. The presence of blood in the cells and smaller air-tubes will be likely to give rise to the subcrepitant and perhaps to a well-marked crepitant rale within a limited space. These signs, suddenly developed in connection with hæmoptysis, and with mitral cardiac lesions, may lead to a diagnosis; but in the cases in which no blood is expectorated, a positive diagnosis is extremely difficult if not impracticable.

Circumscribed extravasation, incidental to bronchial hemorrhage, is not necessarily serious; and perhaps it occurs, to a limited extent, not infrequently in cases of abundant hæmoptysis, followed by recovery. If there be no injury of the pulmonary structures, and the blood simply infiltrate the air-cells, it may be gradually removed by absorption and expectoration, the normal condition being restored, as after solidification from pneumonitis. If due to embolism the hemorrhage may lead to gangrene; or the infarcted portions may become the sites of embolic pneumonia, and the so-called metastatic abscesses. If these results do not follow, and the number and size of the spaces in which the extravasation has taken place be not large, recovery may take place. When, however, the hemorrhage is into the cells, leading to infiltration of the areolar tissue, and the extravasation is considerably diffused, the termination is usually fatal, and death may take place speedily. Other things being equal, the gravity of the symptoms, and the immediate danger, are in proportion to the amount of extravasation.

The treatment of different forms of pneumorrhagia must have reference to the symptomatic indications in particular cases, in addition to analeptic and supporting measures.

Pulmonary Gangrene.

Pulmonary gangrene has already been referred to as occurring in cases of pneumorrhagia and of pneumonitis. It is, however, one of the most infrequent of pulmonary affections. Its infrequency is shown by the following statistics: of the records of 1069 autopsies analyzed by Dr. Lauthna, of Vienna, there were only 5 cases. Of 3437 autopsical records examined by Dr. Fischel, of Prague, there were 75 cases. Fuller states that in the *post-mortem* records in St. George's Hospital, London, for ten years, there were 19 cases. I had met with about 15 cases at the date of the first edition of this work, namely, in 1866.

It is presented in two forms, distinguished as diffused and circumscribed. In the diffused form, the gangrene extends over a considerable space, sometimes involving the greater part or the whole of a lobe. This is the

graver form, and almost of necessity proves fatal. The circumscribed form is that which usually occurs. In this form, the gangrene is limited to a space varying in size from that of a bean to a hen's egg, the limits being sharply defined. It is an extremely grave affection when circumscribed, but recovery takes place in a certain proportion of cases.

The appearances after death differ according to the period when the fatal ending takes place. If the patient die before the sloughing is completed, the gangrenous portion is of a dark, greenish color, friable or diffluent, emitting a characteristic odor, bloodvessels and other traces of organization being destroyed—in short, the portion is dead and more or less decomposed. If the sloughing have been completed, and the decomposed mass removed by expectoration, there remains a cavity corresponding in size to the portion of lung which has been lost. When recovery takes place, restoration is effected as follows: lymph is exuded around the gangrenous mass, and the latter is in this way isolated. The cavity left after the completion of the sloughing is lined by a kind of cyst. Gradual contraction of the cavity ensues, ending, finally, in closure and union, leaving a white line with more or less depression and puckering. The recovery is then complete, with, of course, some diminution of the volume of lung. In some cases cicatrization does not take place, but the cavity remains for an indefinite period. The posterior aspect of the upper portion of the lower lobe is the most frequent site of gangrene.

The occurrence of gangrene as incidental to pneumonitis, and to circumscribed extravasation of blood or pulmonary infarctions, does not suffice to account for it in all cases. It is, probably, sometimes an effect of embolism of a branch of the bronchial artery, the embolus being derived either from the left ventricle or the aorta. Embolism of a branch of this nutrient artery may perhaps occasion such a degree of local anæmia or ischæmia that the part supplied by the obstructed vessel loses its vitality; whereas, when the gangrene is an effect of a hemorrhagic infarction, it is caused by the interruption of the capillary circulation by the pressure of the extravasated blood. The latter explanation is the same as when the gangrene results from pneumonitis. The interruption of the circulation in the second stage of pneumonitis, arising from the pressure of the deposit within the cells, is such that the infrequency of a loss of vitality is surprising. In some cases of embolism of a branch or branches of the pulmonary artery, the occurrence of gangrene is attributed to a specific effect of the emboli; that is, the emboli being derived from a part in which a gangrenous process is going on, this process is reproduced in the parts in which they become fixed. Putrescent morbid products remaining in cavities formed by dilated bronchial tubes (bronchiectasis), are supposed sometimes to lead to gangrene of the proximate pulmonary structures. Gangrene is sometimes attributable to the presence of pus derived from an abscess of the liver, spleen, or kidneys, and from the contents of the stomach involved in the act of vomiting. It may be caused by the pressure of an aneurismal or other interthoracic tumor. It appears sometimes to be an effect of the inspiration of irritating gases.

Causes, however, more general in their operation, are evidently involved in a certain proportion of cases. It occurs oftener in males than in females. It sometimes follows typhus and measles. Intemperance and diabetes involve a predisposition to it. It occurs in a larger ratio among the insane. These facts show that a morbid constitutional state, or a special impairment of the condition of the blood, or a cachexia, enters into the etiology.

These symptoms, in cases of gangrene, will relate measurably to the

general condition or to associated affections. The pulmonary symptoms due to the gangrenous condition, at first, are those which belong to circumscribed pneumonitis, consisting of cough, some pain, and accelerated breathing, and, after a time, an expectoration, more or less abundant, takes place, which is of a dark or greenish color, and emits an intensely fetid odor. This expectoration consists of the debris of decomposed pulmonary substance. The gangrenous sputa may contain elastic fibres visible under the microscope. Vegetable parasites have also been observed. The characteristic expectoration continues for a certain time, and, if the case do not end fatally, is accompanied and followed by a muco-purulent expectoration, more or less copious, which, at length, loses the gangrenous odor, and, gradually lessening, ceases when recovery takes place. While the decomposition and sloughing are going on, the pulse is frequent and feeble, and the patient is considerably or greatly prostrated. Of course, if the gangrene be incidental to pneumonitis, extravasation of blood, tuberculosis, or other affections of the lungs, pulmonary symptoms proceeding from these affections, will precede and accompany the symptoms due to the gangrene.

The diagnosis is to be based chiefly on the characteristic appearance and odor of the expectoration. Prior to the occurrence of this expectoration the condition is not determinable. A gangrenous odor of the breath, without the presence of decomposed pulmonary tissue in the expectoration, is not adequate proof of the existence of the affection, and this fact not being always sufficiently considered, the diagnosis is sometimes made on insufficient ground. In cases of tuberculosis advanced to the cavernous stage, the odor of gangrene in the matter expectorated and in the breath may be produced by the sloughing of pulmonary tissue within the cavities. This is not very uncommon. A superficial slough of a portion of the bronchial mucous membrane may give rise to great fetor of the breath in cases of bronchitis. The latter is the explanation in some cases in which the fetor is of brief duration, and when recovery takes place without phenomena which denote any grave affection. I have met with several cases of this description.

The gangrenous portion of lung, together with the solidification from the exudation of lymph around this portion, furnishes dulness or flatness on percussion within a circumscribed space, which, in view of the most frequent situation of gangrene, will generally be over the scapula below the spinous ridge. Within this space either the respiratory murmur is wanting, or there is a feeble bronchial respiration, with, perhaps, either exaggerated vocal resonance or weak bronchophony. Moist bronchial or bubbling rales are likely to be heard within and around this space. These signs are not available if the gangrene occur in connection with pneumonitis or tuberculosis; but they serve to establish the diagnosis, taken in connection with the characteristic expectoration, if the affections just named be not associated. If the gangrene be circumscribed, and the patient survive the sloughing and removal by expectoration of the decomposed mass, the cavernous signs may be discovered. I have repeatedly found a well-marked cavernous respiration; and I have observed a circumscribed depression in front corresponding to the situation and size of the gangrenous cavity.

As regards prognosis, if the gangrene be circumscribed, and it do not occur under circumstances which are dangerous, irrespective of the gangrene, recovery may take place. The chances of recovery are differently estimated by different writers, which, perhaps, may be accounted for by supposing that the diagnosis of gangrene is not infrequently based on

insufficient grounds. It can hardly be doubted that the result is fatal in a large majority of cases. Hæmoptysis sometimes takes place in connection with the separation of the slough or eschar. I have known the hemorrhage to be so abundant as to prove the immediate cause of death. If the gangrene involve the pleura, perforation of the lung takes place, and pleuritis with pneumothorax is developed. These cases probably always end fatally. I have met with several examples.

The treatment of pulmonary gangrene is to be directed more to the system than to the local affection. The affection never occurs under circumstances which render depletion or other debilitating measures appropriate; on the contrary, such measures can hardly fail to be pernicious. Tonic remedies are indicated, and the sustaining treatment. The diet should be as nutritious as possible, and alcoholic stimulants are to be given with a freedom proportionate to the tendency to failure of the vital powers. The employment of opium, in some form, is important, in order to palliate pain or undue cough, and to allay constitutional irritation. The chlorate of potassa has been suggested as likely to be useful, from its apparent usefulness in gangrenous affections of the mouth and throat. The tincture of the chloride of iron is suggested by the same analogy. The inhalation of the vapor of turpentine poured upon boiling water is extolled by Skoda as exerting a favorable local effect. Others have attributed a curative influence to the inhalation of tar vapor, creosote, and chlorine. These remedies are administered by inhalation much more efficiently in the form of atomized liquids or spray than by means of vapor.

To diminish the offensive odor of the breath, chlorinated water, or a solution of the permanganate of potassa, may be used as a collutory.

Pulmonary Œdema.

Pulmonary œdema is always dependent on other pathological conditions, and is not entitled to be considered as an individual affection. It is, however, an event of not infrequent occurrence, and is important as interfering with the function of respiration, and, in not a few instances, proving the immediate cause of death. The term œdema denotes, in other situations, a dropsical effusion into the areolar tissue; but in œdema of the lungs the transudation is primarily and chiefly within the air-cells, the serum also infiltrating the interlobular structure.

An œdematous lobe or lung is increased in volume and weight; it pits on pressure like the integument in ordinary œdema; on section, a purely serous or sero-sanguinolent liquid escapes in abundance, containing but few air-bubbles, and, on pressing out the liquid, the mass of the lobe, or lung, and its weight are found not to be greater than in health, showing the absence of any solid deposit. Microscopical examination shows the pulmonary structure to be intact. More or less œdema of the lungs is frequently found in post-mortem examinations. It may extend over portions of both lungs, generally, under these circumstances, being situated in the posterior portions, or it may be limited to one lung, in the latter case extending over the whole lung, or confined to one lobe.

The pathological conditions on which it is dependent are various. It is one of the situations of dropsy in cases of degenerative lesions of the kidneys and of acute albuminuria. It is incidental to the pulmonary congestion necessarily induced by cardiac lesions, more especially those which involve mitral obstruction or regurgitation, or both. It occurs in cases in which congestion of the lungs is produced by obstruction of the pulmo-

nary veins from the pressure of an aneurismal tumor. The hypostatic congestion which occurs in low fevers and other diseases in which the blood is impaired, and when patients maintain, for a long time, recumbency on the back, gives rise to it, and under these circumstances it is not infrequently the immediate cause of death. It is generally associated with more or less hydrothorax. It may take the place of hydrothorax if the pleural surfaces are united by old adhesions. In a case of general dropsy succeeding scarlatina, the patient dying from interruption of the respiratory function, or apnœa, hydrothorax existed on one side, and the lung of the other side was highly œdematous, the pleural sac, in the latter side, being abolished by universal close adhesions due to an old pleurisy.

The symptoms of œdema are increased frequency of the respirations and dyspnœa, in proportion to the extent of lung affected, together with more or less cough and serous expectoration, or bronchorrhœa. The displacement of air in the air-cells by liquid, gives rise to dulness or flatness on percussion over a space corresponding to the œdematous portion of lung, and within this space, the respiratory murmur is lost, or it is feebly bronchial or broncho-vesicular. The vocal resonance may be increased. The presence of liquid in the smaller bronchial tubes is denoted by fine mucous or subcrepitant rales. It is stated that a true crepitant rale may be produced, but this must be extremely rare. The diagnosis is to be based on dulness or flatness on both sides of the chest, associated with moist bronchial rales, pneumonitis being excluded, and the existence of Bright's disease, cardiac lesions, and other causative conditions, being considered.

The treatment must have reference to the circumstances under which it occurs. Occurring in connection with disease of the kidneys, those measures are indicated which are applicable to dropsical effusion in other situations, viz., hydragogue cathartics, and sudorifics, selected and regulated according to the circumstances belonging to individual cases. When incidental to disease of the heart, the main reliance is upon revulsive measures, in connection with such remedies as the condition of the heart may claim irrespective of this result. In the cases in which it is dependent on adynamia and an impaired condition of the blood, tonic and sustaining measures are called for. The liability of its occurrence in connection with hypostatic congestion, in fevers and other protracted diseases, accompanied by feebleness of the circulation and depression of the vital powers, renders it an important part of the treatment of these diseases to see that the patient be not allowed to lie constantly in one position. The position of the body should be frequently changed, in order to obviate the gravitation of blood to the dependent portions of the lungs.

The name *acute* pulmonary œdema may be applied to certain cases in which the œdema occurs suddenly and to such an extent as to give rise to great dyspnœa. It may prove quickly fatal by apnœa. In such cases, prompt and efficient measures of treatment are called for, namely, an active hydragogue purgative, with dry cups to the chest, followed by sinapisms. The hot-air bath may be employed if hydragogues are contraindicated by the feebleness of the patient. I have known the inhalation of oxygen to afford marked relief. In my experience the acute form has occurred only in connection with renal disease.

Carcinoma within the Chest.

Intra-thoracic carcinoma is rare, and is almost always secondary to carcinoma in other situations. Walshe states that it is especially apt to follow cancer of the testicle. In a considerable proportion of cases it

follows the removal of a cancerous breast. The medullary or encephaloid is the variety usually occurring within the chest. Scirrhus in this situation very seldom occurs, and the colloid variety has been known to occur in only a few instances.

Pulmonary carcinoma is said to be infiltrated when it extends over a considerable, or, sometimes, a large, space, the substance of the lung being supplanted by the morbid growth. Oftener it is in the form of nodules, varying in size from that of a pea to an orange, the boundaries of which are sharply defined, and which are more or less numerous, being usually disseminated throughout both lungs. In either form, the physical condition of the affected part or parts is solidification or induration. After a time, which is very variable in duration, softening and ulceration ensue. Pulmonary cavities may be produced. Circumscribed pleurisy is usually induced. In some cases, perforation of the pleura takes place, and pneumo-hydrothorax is the result. The lymphatic glands within the chest, and also those of the neck and axilla, are apt to become involved. If the carcinoma be unilateral and diffused over the greater part or the whole of one lung, it leads to notable contraction of the affected side. Hemorrhage and gangrene are incidental events occurring in some cases. The symptoms are pain, cough, and expectoration, the latter becoming muco-purulent, and sometimes presenting an appearance of currant jelly. This appearance is somewhat diagnostic.

The diagnosis is to be based on the symptoms, taken in connection with the signs of solidification, and sometimes the cavernous signs. The physical evidence is not very distinctive of this affection. Pulmonary tuberculosis and chronic pneumonitis are to be excluded by a careful investigation with reference to the history, as well as the existing symptomatic phenomena. The coexistence of carcinoma in some other situation, or its previous existence, is to be taken into account in arriving at a diagnosis.

When the primary seat is exterior to the lungs, it may be presented in the form of nodules, more or less numerous, varying in size from that of a pea to that of an orange, which may be confined to one side, but usually are in both lungs; the pleural surfaces are sometimes thickly studded with these. Or, it may be in the form of one or more tumors, which attain, in some instances, to a great size, occupying the greater part or the whole of one side (oftener the right), and sometimes encroaching more or less on the other side of the chest. The lungs are displaced, and undergo compression in proportion to the extent of the carcinomatous growth, and the affected side may be more or less dilated. The dilatation, in some cases, is increased by liquid effusion due to coexisting pleuritis. Under these circumstances the affection is liable to be mistaken for empyema or chronic pleuritis. This error has happened to physicians of skill and experience in the physical exploration of the chest.

The presence of tumors, great or small, gives rise to dulness or flatness on percussion, with either suppression of the respiratory murmur, or the modifications which denote solidification. The tumors may be so situated as to give rise to symptoms and signs proceeding from pressure on important parts other than the lungs. The heart may be displaced. The calibre of the trachea or bronchi may be diminished. Aphonia or laryngeal spasm may be induced, if the recurrent nerve be involved. Congestion limited to the upper extremities, head and neck, and subcutaneous œdema, denote obstruction of the superior vena cava. Pressure on the pulmonary veins may give rise to bronchorrhagia and œdema of the lungs. Compression of the œsophagus occasions difficulty in the ingestion of food and drinks. These results of pressure on adjacent parts, however, are common to other

than carcinomatous tumors, for example, aortic aneurisms. A cancerous tumor, circumscribed and situated in the tract of the aorta, may simulate the physical signs of aneurism. It may pulsate and give rise to a murmur. I am satisfied, by my own observations, that it may occasion a double murmur, that is, a systolic and a diastolic murmur.

I shall content myself with this brief reference to carcinoma within the chest. For a full consideration of the points involved in the diagnosis, the reader is referred to works which treat *in extenso* of thoracic affections. In a practical view, only the diagnosis of carcinoma claims much consideration. The affection is hopeless, and the measures of treatment have reference only to the palliation of symptoms, and measures to prolong life. According to Lebert, the duration of life varies from one to two years, and, in some cases, death does not take place for several years.

Hydatids.

Among the extremely rare affections of the pulmonary organs belong hydatid productions. These may be developed within the lungs, or they have been developed in the liver and made their way through the diaphragm into the pulmonary organs, in the manner in which hepatic abscesses are sometimes evacuated into the bronchial tubes, circumscribed peritonitis and pleuritis taking place, and leading to adhesions which prevent the evacuation from taking place into either the peritoneal or pleural sac.

Acephalocysts within the lungs may remain for a variable period latent, that is, giving rise to few or no pulmonary symptoms. Sooner or later, however, they excite inflammation of the surrounding parenchyma and bronchial tubes, and then occasion pain, cough, expectoration, febrile movement, etc. They may be discharged by ulceration into the bronchial tubes, leaving pulmonary cavities. The affection is likely to be mistaken for pulmonary tuberculosis. Microscopical examination of the matter expectorated may show the hooklets of echinococci, and without this demonstration the diagnosis is impracticable. The question as to the primary seat of the cysts is to be settled by the previous history, which, if they come from the liver, will show the existence of hepatic trouble prior to the occurrence of pulmonary symptoms.

The presence of hydatids in the lungs always involves great danger; the danger is greater when they are derived from the liver than when they are developed within the lungs. Fuller estimates that of cases of the latter recovery takes place in the proportion of one-half. There is no special plan of treatment. Palliative and sustaining measures are to be adapted to the circumstances of individual cases.

Hypertrophy and Atrophy of the Lungs.

Pulmonary hypertrophy can hardly be said to exist under circumstances rendering it of much importance in a practical point of view. Increase of the volume of the lungs from distension or dilatation of the air-cells is not hypertrophy, but, on the contrary, it is associated, in cases of emphysema, with atrophy. True hypertrophy, that is, an actual increase of the tissues forming the pulmonary organs, is stated by Rokitansky and others to take place when, owing to abolition of the respiratory function of one lung, the other lung takes on an increased functional activity, the latter becomes hypertrophied. Hypertrophy is also described by Skoda and Virchow as occurring in cases of prolonged pulmonary congestion caused by mitral

cardiac lesions or by dilatation of the right ventricle. Under these circumstances, the increase of the pulmonary tissues is at the expense of the capacity of the air-cells; the tissues present a brownish color, and the pigmentary deposits are unusually numerous and large.

Atrophy of lung is a lesion involved in the form of emphysema distinguished as atrophous or senile, and has been already noticed in that connection.

CHAPTER IX.

Affections of the Larynx and Trachea. Points relating to the Anatomy and Physiology of the Larynx which are involved in the consideration of Diseases in this situation. Acute Simple Laryngitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Sabacute Laryngitis. Chronic Laryngitis. Laryngitis with Exudation of Lymph—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Œdema of the Glottis. Spasm of the Glottis. Nervous Aphonia. Morbid Growths.

IMPORTANT diseases affecting the respiratory apparatus are seated above the chest, viz., in the larynx and trachea. Diseases of the larynx frequently involve the trachea, but it is rare for the latter to be affected without the former, and it will suffice to consider tracheal affections incidentally in treating of those of the larynx.

Certain anatomical and physiological points pertaining to the larynx are to be kept in mind with a view to a clear apprehension of the diseases in this situation. The larynx is composed of a collection of cartilages, viz., the cricoid, thyroid, arytenoid, and epiglottis. The latter was formerly supposed to be essential as a protection against the entrance of food and drink into the laryngeal cavity during the act of deglutition; the removal of this appendage, however, in inferior animals, has shown that its loss does not occasion serious inconvenience. It has occurred to me to meet with a hospital case in which this part was completely destroyed by syphilitic ulceration, as determined by the touch and the laryngoscope. The patient, a young female, was for some time under my observation at Bellevue Hospital. So long as ulceration existed, there was considerable difficulty arising from spasm of the glottis, excited by contact with food and drink, and deglutition was performed with the least annoyance while the patient was lying on the back. But, after the ulceration had healed, the difficulty nearly ceased, liquids and solids being swallowed without much inconvenience. The quality of the voice underwent some change, and the patient stated that she had not the power of producing notes in singing as before.

The small size of the *rima glottidis* is an important point in connection with laryngeal diseases. In the adult male, after death, it is a triangular space an inch in length, and, at the base, about a quarter of an inch in width, the size being still smaller in the female and child. The dimensions, however, vary with the two respiratory acts. When examined in a living animal, the vocal chords are found to separate widely in inspiration and return in expiration, forming the respiratory movements of the glottis. The respiratory movements take place from a reflex influence communi-

cated through the recurrent nerves. These points are of interest and importance in their practical applications.

Other movements of the muscles of the larynx are produced by volition in the acts of speaking. The larynx being the seat of the voice, modifications of vocal sound constitute important symptomatic phenomena of disease. The experiments of Bernard have shown that in producing the movements concerned in phonation the will acts through branches of the spinal accessory contained in the recurrent laryngeal nerves. The laryngeal muscles are subject to spasm and paralysis.

The solidity of the walls of the larynx is an important point in connection with certain affections. The cricoid and thyroid cartilages do not readily yield to internal pressure, and hence arises obstruction from the presence of morbid products which encroach upon the small space between the vocal chords. Another point to which reference will be made is the abundance of loose areolar tissue beneath the mucous membrane, especially above the vocal chords; this is much more marked in the adult than in the child, a fact which will serve to account for certain differences as regards the effects of disease during and after infantile life.

Of the affections of the larynx, those involving inflammation will be first considered. Inflammation here may be simple in character, that is, not distinguished by any unusual features save those which are incident to the situation of the affected mucous membrane. On the other hand, it may be of an unusual character, viz., accompanied by an exudation of lymph. The latter will be considered under a separate head. Simple inflammation may be either acute, subacute, or chronic. These three varieties are to be considered separately. The appropriate name for inflammation affecting the larynx is *laryngitis;* this name should take the place of the terms *angina* and *cynanche*, which were formerly in vogue, but now rarely used. The term *croup* is applied to laryngitis with the exudation of lymph, and also to cases of simple laryngitis and of a non-inflammatory affection, viz., spasm of the glottis, occurring in children. The first of these affections embraced by the term, is sometimes distinguished as *true croup*, while the others are called, by way of distinction, *false croup*. The term is an unfortunate one, and tends to produce confusion. I shall consider the several affections which the term embraces, not under the head of croup, but separately under their appropriate names.

Acute Simple Laryngitis.

Anatomical Characters.—The anatomical characters are essentially the same as in bronchitis, so far as they relate to the mucous membrane. The morbid changes may be limited to this membrane, or they may extend to the submucous areolar tissue. In the former case, the inflammation has been called erythematic, from its analogy to erythema of the skin. In the latter case the products of inflammation, lymph, and perhaps pus, are situated beneath the membrane. In the liability to this extension of inflammation laryngitis differs from bronchitis, the difference being probably due to the greater abundance of areolar tissue beneath the laryngeal mucous membrane.

Cases of acute laryngitis differ as regards the point just stated, and the distinction is practically important. Some writers, following Cruveilhier, have based thereupon a division of the disease into two varieties, viz., mucous or erythematic laryngitis, when the changes are confined to the membrane, and submucous or œdematous laryngitis, when inflammatory products are deposited beneath the membrane. This formal division is hardly ne-

cessary, but the gravity of the disease depends, in a great measure, on the presence of submucous infiltration. The latter occurs to a much less extent in children than in adults, owing, probably, to the fact that the submucous areolar tissue is less abundant in early life. The epiglottis frequently participates in the inflammation, and may be seen during life to be enlarged and reddened.

Clinical History.—The symptoms of acute laryngitis are intelligible when the morbid changes are considered in connection with the small size of the *rima glottidis* and the unyielding walls of the larynx. Simple swelling of the mucous membrane may produce more or less distressing symptoms and danger due to narrowing of the aperture of the glottis. But, with submucous infiltration added, the obstruction is increased, and will be likely to prove fatal by strangulation. The obstructive effect of the morbid changes explains the symptomatology and danger. The chief element of danger is the submucous infiltration. This takes place in some cases and not in others; and it occurs in varying degrees, the severity of the symptoms and the danger being in proportion to its amount. The submucous areolar tissue, however, may be infiltrated with serum without an extension of inflammation beneath the membrane, and the presence of lymph or pus in the latter situation, in cases of acute laryngitis, is infrequent.

The development of the disease may be preceded by subacute laryngitis, or a common cold. The voice is at first hoarse, and, with the development of acute inflammation, is lost. The aphonia is accompanied with a stridulous cough, and a small expectoration of glairy mucus which may be streaked with blood. Febrile movement is more or less intense or it may be wanting. These symptoms may exist without notable difficulty of breathing, provided the changes are limited to the membrane, and the swelling be not great.

With a greater amount of swelling, together with submucous infiltration, labored respiration and dyspnœa are added. The obstruction affects both inspiration and expiration, but more especially the former, owing to the fact that the infiltration is greatest above the rima where the areolar tissue is most abundant. The respiration is stridulous or noisy. The patient complains of a sense of constriction at the larynx, or feels as if the cavity were filled with a foreign substance. There is frequently more or less difficulty in deglutition. Fluids, by coming into contact with the inflamed epiglottis, excite cough and add to the distress. The labor of breathing and dyspnœa are increased by the occurrence of spasm of the arytenoid muscles. The exacerbations of distress from obstruction are due chiefly to a spasmodic element.

In cases of acute laryngitis with great obstruction, the suffering is intense. The face and eyes are swollen and congested, the countenance denotes anguish, and, after a time, lividity occurs. The distress is much increased during the exacerbations caused by spasm, and in the intervals of comparative ease the patient manifests drowsiness, but is rarely able to obtain refreshing sleep. With the muscular efforts to enlarge the aperture of the glottis, the larynx rises and falls in the acts of inspiration and expiration. There are frequent efforts to cough and expectorate, as if to get rid of an accumulation within the larynx. The cough may be dry and croup-like, but is oftener husky or abortive. The larynx is sensitive to pressure. Pitting over the *pomum adami* has been observed. The respiratory acts are less frequent than in health. In a case which I have recorded they were twelve per minute.

With these symptoms, in a large proportion of cases the disease has been found to end fatally. The mode of dying is by apnœa, and it may take place gradually, or suddenly in an exacerbation of unusual violence.

Assuming that other affections do not coexist, the symptoms, in addition to those which relate directly to the laryngeal obstruction, are incidental to febrile movement, deficient oxygenation of the blood, and the suffering which belongs to the disease. Slight delirium may occur toward the close of the disease if it be prolonged, but, in general, the mental faculties are unaffected.

Pathological Character.—In simple acute laryngitis, the inflammation has no special characteristics. The severity and danger are not owing to the intensity or extent of the inflammation. The same amount of inflammation in other situations would constitute a trivial affection. The gravity is due to the fact that the usual results of inflammation in this situation obstruct the passage of air through the larynx, in consequence of the small size of the rima glottidis and the unyielding laryngeal walls. In children, simple acute laryngitis gives rise to croupy cough and respiration, and hence, this is one of the different affections commonly embraced under the name croup. Ware, in his admirable papers on the subject of croup, distinguished this variety as *inflammatory croup.*

Causation.—Acute laryngitis in the adult is so rare that practitioners of considerable experience may have never met with an example of it. It is less rare in infants and children than after adult age. Its infrequency is remarkable in view of the frequent occurrence of inflammation in the pharynx; and the fact exemplifies the principle of conservatism involved in the law by which inflammation does not tend to extend from one part to other parts, although in immediate proximity. I have seen a case in which the pharynx was laid open by a gunshot wound in the neck, so that the top of the larynx could be seen through the wound, and yet, during the progress of recovery, there was no evidence of the slightest laryngeal inflammation.

Occasionally, however, laryngitis is developed in connection with pharyngitis. This was observed in some cases of the so-called epidemic erysipelas, or "black tongue," which formerly prevailed in many parts of this country. I have known it to occur, in connection with the pharyngeal affection, in scarlatina. The laryngitis which, in a subacute form, is common in rubeola, sometimes becomes acute. Acute inflammation may be excited in variola by the occurrence of the eruption in this situation. Under the several circumstances just named, it is a secondary affection. It may occur as a primary affection after exposure to cold and wet, as in the case of Washington.

It might be conjectured that excessive use of the voice would be likely to predispose to this affection, but clinical observation furnishes no proof that such is the fact. It may be produced, traumatically, by the inhalation of irritating vapors. A distinguished professor of chemistry, some years ago, lost his life by laryngitis caused by accidentally drawing into the larynx a corrosive acid through a pipette, the extremity of which had been broken.[1] A number of cases have been reported in which young children have suffered and died with this disease produced by sucking boiling liquid and steam from the spout of a water- or teapot.

[1] The late Prof. Palmer, of Woodstock, Vt.

Diagnosis.—The diagnostic characters of acute laryngeal inflammation are the loss of voice and the husky, stridulous cough, in connection with the febrile movement and other symptoms. That the labor of breathing and dyspnœa are due to the obstruction of the larynx, is shown by the sensations of the patient, the diminished frequency of the respiratory acts, and the absence of physical signs denoting pulmonary disease. In proportion as the aperture of the glottis is narrowed, the respiratory murmur will be weakened, and this affords a better criterion of the amount of obstruction than the sufferings of the patient. The only difficulties in diagnosis relate to the discrimination of simple acute laryngitis from laryngitis with the exudation of lymph, from œdema of the glottis, and from spasm of the laryngeal muscles. In arriving at the conclusion that simple acute laryngitis exists, the affections just named are excluded by the absence of distinctive circumstances belonging to the clinical history of each. Suffice it to say here that the presence or absence of the exudation of lymph in cases of laryngitis is generally determinable; that œdema of the glottis may be demonstratively ascertained; and that spasm without inflammation, or with only subacute inflammation, is wanting in characters which are essential to the diagnosis of acute laryngitis.

Prognosis.—Acute laryngitis in the adult is a grave affection. The gravity, as already stated, depends mainly on the occurrence of submucous infiltration. Cases without this contingency occur and may end favorably without very alarming symptoms. The suffering in these cases arises chiefly from spasm. If the constant obstruction—*i. e.*, obstruction exclusive of that due to spasm—be sufficient to interfere greatly with respiration, the tendency is to a fatal result. A proportion of such cases will end fatally if life be not saved by timely surgical interference. The course of the disease in fatal cases is rapid. It has been known to prove fatal in seven hours. The duration rarely exceeds a week.

In young subjects this disease is less severe and less likely to prove fatal than in adults, notwithstanding the smaller size of the rima glottidis in early life, the difference being probably due to the fact that submucous infiltration occurs to a less extent in children. Of eighteen cases, included among the cases of so-called croup analyzed by Ware, in not one did the disease end fatally.

Treatment.—The treatment of acute laryngitis relates to general and local measures. The general measures embrace those designed to lessen the intensity of inflammation, limit exudation, promote resolution, and the absorption of exuded products. The measures which may be employed for these ends are the same as in acute inflammation in other situations. It may be doubtful how far the ends are attainable, still, the measures which are supposed to be in any degree operative are not to be withheld in a disease involving so much danger as this. The employment of bloodletting is to be guided by the same principles as in other inflammations, but the evils or danger of abstracting blood freely are not as great as in certain other inflammations, for example, pneumonitis or pleuritis, because there is not the amount of morbid effects to be recovered from, and it is therefore not so important to spare the vital powers for the processes of restoration. The danger in acute laryngitis, it is to be borne in mind, is not from the extent or degree of the inflammation, nor from the lesions which it may induce *per se*, but it is incidental to the seat of the inflammation. And if a fatal result take place, the dying is by apnœa, not by asthenia. But in the use of bloodletting and other depressing measures,

this consideration must be kept in view: the patient's strength is not to be so far diminished as to incapacitate for the prolonged muscular exertions which the labor of breathing may require. Bloodletting should never be practised after lividity of the prolabia and face gives evidence of deficient oxygenation of the blood. Under these circumstances, a fatal result would be hastened by abstracting blood.

The bowels should be moved efficiently by cathartics of the saline class. Nauseant or the direct cardiac sedatives are indicated as in other inflammations. Nauseant remedies should not be carried so far as to produce vomiting, which will add greatly to the distress, and tend to aggravate the inflammation. If antimony be used, it should be given largely diluted, to avoid its local action on the throat.

Mercurialization may be advocated in this, as in some other affections, on the following ground: Although the antiphlogistic and sorbefacient powers of mercury have doubtless been greatly over-estimated, it is not certain that it exerts no remedial influence in these directions. So long, therefore, as there is room to suppose that it may be useful in any measure, it should be employed in an affection like this, which frequently tends rapidly to destroy life by apnœa. The general depressing effect and other evils of mercurialization are of little comparative account, provided the remedy will prove in any degree useful in its influence on the local affection. If mercurialization be determined on, it should be induced early and rapidly, either by large doses guarded with opium, or by small doses repeated at short intervals, mercurial inunction being added.

Remedies to palliate spasm and cough are indicated. The spasmodic element may be more or less prominent. Its degree of prominence is shown by the frequency and severity of the paroxysmal distress; whereas, the amount of obstruction due to the swelling and infiltration is shown by the labor of breathing in the intervals between the paroxysms or exacerbations. Opium and antispasmodic remedies are important in proportion to the amount of suffering from spasm, but opiates should not be carried so far as to blunt the perception of the want of breath.

In the foregoing remarks on the general measures of treatment, reference has been had especially to idiopathic or primary laryngitis. When the affection occurs as a complication of scarlatina, rubeola, or variola, and if it be associated with pulmonary or any other important disease, the same measures may not be admissible. This statement applies to bloodletting, mercurialization, and other depressing measures. Inflammation of the trachea frequently, if not generally, coexists, and bronchitis may be developed in accordance with the law respecting the extension of inflammation in the air-passages, viz., that it tends to travel downward, and but rarely upwards. Of course, the general symptoms, febrile movement, etc., will be increased in proportion to the extent of mucous surface inflamed.

The local measures of treatment embrace fomentations or poultices applied to the neck, with a blister, perhaps, applied over the sternum; and either the atmosphere of the apartment should be charged with steam, or the vapor of hot water inhaled by means of a convenient apparatus. The application to the throat of compresses dipped in ice-water, and renewed at intervals of a few minutes, is a measure which may be tried with safety; and, if it afford relief, it may be often repeated, being continued as long as it is agreeable to the patient. Early in the disease it may act favorably as an antiphlogistic; and, afterward, it may afford relief by diminishing spasm.

Topical applications to the larynx may be made by means of a probang

suited for that purpose. I have been assured by an intelligent medical student, who had experienced the disease, that he derived much temporary relief from the frequent introduction of a sponge saturated with a strong solution of the nitrate of silver. The application was repeated every three or four hours. The relief was probably due to the morbid sensibility of the part being blunted by the topical application, and the liability to spasm thereby lessened.

Tracheotomy is to be employed in this disease, provided the obstruction becomes so great as to render the danger of death imminent. Patients should never be allowed to die from strangulation for want of timely surgical interference. If the danger be purely or chiefly from apnœa, this operation will often prove the means of saving life. The important question is—when is it to be performed? It should not be delayed after permanent lividity occurs, that is, lividity due to the obstruction caused by the swelling and infiltration irrespective of spasm. Persisting lividity denotes imminent danger, and subsequent delay impairs the probability of success from the operation.

After convalescence is established, the recovery of the voice is slow, the pitch and quality remaining altered for some time.

The treatment of acute laryngitis in children, owing to its being a less severe and grave affection than in the adult, claims less vigorous measures. Cases frequently, if not generally, do well with simple palliative measures. Emetics may be important in order to effect the removal of viscid mucus from the larynx. Death may be produced solely by obstruction due to the accumulation of mucus in this situation. It would hardly be supposed that the larynx may be so tolerant of obstruction from this source, that, occurring in a healthy child, efficient efforts of coughing would not be excited, but life be destroyed by slow apnœa; yet a case exemplifying the fact has fallen under my observation.

Subacute Laryngitis.

Subacute inflammation of the larynx is of frequent occurrence, either as preceding the development of bronchitis, or the inflammation not extending to the bronchial tubes. It characterizes certain cases of a common cold. The inflammation is of a low grade of intensity, or erythematic. There is either hoarseness or aphonia, with cough, and an expectoration at first transparent and viscid, and, afterward, opaque, thick, and loose. There is no obstruction to respiration. Laryngeal spasm in the adult is rarely excited. There is little or no febrile movement.

It is only important as involving some liability to an increase in the intensity of the inflammation or the development of the acute affection. But the liability to this is small. The measures of treatment are those indicated in cases of bronchitis, or a cold.

Subacute laryngitis exists in a certain proportion of the cases of so-called croup. Ware distinguished these as cases of catarrhal croup. The croup-phenomena are due to spasm, the laryngitis being an unimportant element. This variety of so-called croup is unattended by danger, however violent may be the symptoms referable to spasm.

Chronic Laryngitis.

Chronic laryngitis occurs much more frequently than the acute form; it occurs, therefore, without having been preceded by acute laryngitis. Acute laryngitis, in fact, if it do not destroy life, ends in recovery, with-

out eventuating in the chronic affection, and, on the other hand, in chronic laryngitis, the inflammation rarely, if ever, becomes acute.

Chronic inflammation leads to thickening of the mucous membrane, and ulcerations more or less deep and extensive. The vocal chords are sometimes partially or completely destroyed by the ulcerative process, and sometimes the destruction extends to the muscles, and even cartilages. The epiglottis may be involved in the inflammation and ulceration. In some cases suppurative inflammation is developed primarily between the perichondrium and cartilage. Niemeyer describes this under the name laryngeal perichondritis. Owing to the detachment of the perichondrium, necrosis of the cartilage may take place.

In the vast majority of cases, chronic inflammation in this situation occurs in connection with either syphilis or pulmonary tuberculosis. The localization of syphilis in this part is rare, so that, as a rule, chronic laryngitis is associated with tuberculous disease of the lungs. The exceptions to this rule are so infrequent that the existence of chronic laryngitis constitutes presumptive evidence of the existence of phthisis. Moreover, syphilitic laryngitis, in general, follows a characteristic affection of the pharynx; the disease, in fact, extends from the latter situation into the larynx, and involves the epiglottis. In cases of pulmonary tuberculosis, with chronic laryngitis, it was formerly supposed that the latter preceded the former, and that the disease extended from the larynx to the lungs. The term *laryngeal phthisis* was used to distinguish the affection in these cases. Improvement in the means of detecting a tuberculous deposit in the lungs, however, has led to a knowledge of the fact that the laryngitis in these cases is secondary, the pulmonary disease always being first developed.

The most characteristic of the symptoms relate to the voice. It becomes either hoarse, husky, or stridulous, and it may be lost, that is, there is difficulty of speech (dysphonia) or extinction (aphonia). If aphonia exist, the patient speaks in a husky whisper. The extent to which the voice is affected is not a criterion of the extent to which the vocal organs are damaged by ulceration. Slight ulcerations and thickening will lead to great huskiness and even extinction of the voice. If notable hoarseness exist, more or less destruction of the vocal chords, enlarging the *rima glottidis*, may be suspected.

As regards cough, its prominence, as a symptom, varies in different cases. It is modified like the voice, that is, it is either hoarse, husky, or stridulous. The expectoration, also, varies. It may be slight, or more or less abundant. Its characters may be those of mucus, muco-purulent matter, or pus. Not infrequently it presents bloody streaks, and it may be fetid. The bloody streaks and pus point to ulceration; the fetor points to caries of the cartilages. Cough and expectoration, however, it is to be borne in mind, are measurably due to the tuberculous affections of the lungs, with which the laryngitis is generally associated. Some cases of tuberculous laryngitis are characterized by violent paroxysms of cough, resembling those of whooping-cough, and vomiting is apt to occur during the paroxysms.

A marked difference in different cases relates to deglutition. In some cases the act of swallowing is attended with no inconvenience; but in a certain proportion of cases it is a source of great distress. The passage of food and drink causes pain, excites spasms of the glottis, thus occasioning distressing dyspnœa, and frequently liquids are returned through the nostrils. Patients are obliged to confine themselves to the blandest articles of diet, and even these are sometimes ingested with so much difficulty

that death is hastened by innutrition. This difference, in different cases, depends on the situation of the ulcerations, these being situated sometimes above the vocal chords and upon the epiglottis, where the ulcerated surface comes in contact with the food and drink in the act of swallowing, and sometimes sufficiently below the top of the larynx to be secure from this source of irritation.

The diagnosis of chronic laryngitis is sufficiently easy; the morbid characters of the voice at once indicate the affection. Its connection with pulmonary tuberculosis is to be determined by a physical exploration of the chest, together with an examination into the previous history and symptoms. If pulmonary disease be excluded, the syphilitic source of the affection is to be investigated. The affection may be regarded as idiopathic in cases in which both syphilis and phthisis can be excluded; but, as already stated, such cases are extremely rare.

The prognosis in cases of chronic laryngitis will, of course, have reference to its pathological associations. Its connection with phthisis does not render the latter disease more rapidly progressive; on the contrary, the progress of the tuberculous affection of the lungs is, as a rule, more slow with, than without, this complication. Occurring in this connection, however, the laryngitis is, I believe, never fully recovered from. The inflammation and ulcerations usually continue, but, if not, the voice remains permanently more or less impaired. Considerable improvement may take place in cases of tuberculous laryngitis, although the affection continues. Chronic laryngitis, dependent on syphilis, offers a better prospect of recovery. The voice, however, after recovery, will be likely to remain permanently affected.

In my experience, cases of tuberculous laryngitis have never presented notable embarrassment of breathing from obstruction. In not a few of the cases, however, of syphilitic laryngitis which I have seen, there has been sufficient stenosis to render respiration more or less labored; and in some cases, there supervened a sufficient amount of obstruction to threaten life by apnœa. In a considerable number of cases which have come under my observation at Bellevue Hospital, the operation of tracheotomy has been resorted to, and, apparently, the lives of patients thereby saved. It has sometimes been resorted to more than once in the same case.

The treatment of chronic laryngitis, as regards general measures, will have reference to its pathological relations. In the great majority of cases, the treatment must be that indicated by the coexistence of pulmonary tuberculosis. If the affection be traceable to syphilis, the anti-syphilitic remedies are called for, viz., mercury and the iodide of potassium.

As regards local measures, counter-irritation over the neck by means of the croton oil or small blisters is sometimes useful, even in cases of tuberculosis. The local treatment, however, relates more especially to applications to the affected part: that is, within the larynx. The injection of medicated liquids and the insufflation of remedies in the form of a dry powder have been employed for this purpose. Both these means are unsatisfactory, owing to the difficulty of limiting the application to the diseased parts, and to the cough and spasm which they are liable to excite. A more satisfactory method is the introduction of a sponge attached to a probang, properly curved, as practised first by Dr. Horace Green.

Heretofore there has been much discussion respecting the feasibility of passing the sponge within the larynx, and there are those who still maintain that it is impracticable. It is true that the operation is extremely difficult, if, indeed, it be practicable, on the cadaver, and the scepticism

of some as to the feasibility of the operation on the living body is based on this fact. But the enlargement of the glottis, which takes place in the act of inspiration, divests the operation of the difficulty which attends its performance after death. It is during the act of inspiration that the introduction must be made. During this act, as is well known, foreign bodies of large size are sometimes drawn with the inspired breath into the air-passages. I do not doubt that the sponge is readily passed into the larynx with proper knowledge and skill, but doubtless practitioners often deceive themselves, pushing the instrument into the œsophagus instead of the larynx.

The topical remedy most frequently applied by means of the sponge is the nitrate of silver. A strong solution is commonly used, viz., from one to two scruples to the ounce of distilled water. The sponge wet in this solution is carried between and below the vocal chords. Spasm of the glottis occurs, and the liquid, being expressed from the sponge, comes into contact with the whole of the interior surface of the larynx. This application is sometimes beneficial, affording immediate and marked relief. It may then be repeated from time to time. In many cases, however, no relief is afforded, and in these cases, after a fair trial, it is useless to persevere in it.

Tracheotomy is to be resorted to in cases of syphilitic laryngitis whenever obstruction occurs sufficiently to endanger life.

The recent introduction of the laryngoscope has proved highly serviceable in the diagnosis and treatment of laryngeal affections. By means of this instrument the nature and seat of lesions within the larynx may be ascertained, and the knowledge thus obtained affords aid in judging as to the propriety of topical applications, and in showing the particular points at which they are to be made. The laryngoscope, in fact, may be said to have, in a great measure, transferred the interior of the larynx from the domain of medicine to that of surgery, by rendering this part open to inspection, and making the information thus obtained available for surgical operations. By inspection of the parts within the larynx, lesions may be excluded, and in this way laryngoscopy is sometimes of practical advantage. The presence or absence of foreign bodies may by this means be ascertained. Inspection of the glottis is useful in order to determine whether paralysis of the laryngeal muscles exists or not. Moreover, the characteristic appearances on inspection enable the experienced observer to differentiate thereby syphilitic disease. For a description of these the reader is referred to other works.

Laryngitis with Exudation.

Laryngitis attended with an exudation, occurring for the most part in children, is commonly known as true croup. It occurs, also, as an occasional complication in diphtheria, an epidemic disease characterized by inflammation, with exudation, of the pharynx, and of the mucous membrane in other situations. As belonging to the clinical history of diphtheria, it will be considered in treating of this disease in another section of this work. Suffice it to say here that, as concerns the laryngitis, it is essentially the same in diphtheria and in the affection called croup; yet, taking other circumstances into account, diphtheria and croup are quite different diseases, and the former is more appropriately placed elsewhere than among diseases affecting the respiratory apparatus. In treating, therefore, now of laryngitis with exudation, reference is had to the affection commonly known as true croup. The exudation is generally regarded

as identical with fibrin, and it is often called coagulable lymph. E. Wagner, and Cornil and Ranvier, however, affirm that it consists of epithelial cells infiltrated by an albuminoid substance. Other pathologists do not concur in this statement. Practically the question is not of great importance.

The term croup, as already stated, embracing affections differing widely in pathological character and importance, tends to produce confusion, and it is desirable that as the name of a disease, the term should become obsolete. The term denotes any affection with a peculiar cough called the *croupal cough;* a cough shrill, barking, crowing, as if the sound were produced within a metallic tube, the *tussis clangosa* of Cullen, and accompanied frequently by sonorous or stridulous breathing. Whenever the cough and respiration in children present the croupal character, they are said to have croup. This croupal cough and respiration accompany the affection under present consideration; but it may also accompany, in children, ordinary acute laryngitis, subacute (catarrhal) laryngitis, and spasm of the glottis without any laryngeal inflammation. Ware, in his valuable papers on croup, using this term in its comprehensive sense, recognized four varieties corresponding to the four different pathological conditions just stated. He called these varieties membranous, inflammatory, catarrhal, and spasmodic croup. The first of the four varieties is *true* croup, and the other varieties belong under the head of *false* croup. This division is true to nature, were we to continue to use the term croup in the comprehensive sense in which it has been and is still commonly used.

Laryngitis with an exudation has been called by various names other than true croup, such as membranous, diphtheritic, exudative, fibrinous. Each of these names denotes the characteristic feature of the disease. I prefer the simple expression which I have adopted. The characteristic feature referred to is the exudation on the inflamed mucous surface, forming what is commonly called a false membrane. This is diffused over the inflamed surface, and, for a time, adheres pretty closely to the mucous membrane; but after several days, it becomes loosened, and is finally thrown off. It is sometimes detached and reproduced. The exudation may not extend below the larynx, but, as a rule, it takes place in the trachea; in other words, the laryngitis is accompanied by tracheitis. Not infrequently bronchitis coexists, and the exudation may form within the bronchial tubes. In the vast majority of cases, the exudation exists on the epiglottis, and, to a greater or less extent, within the pharynx. This fact is of much practical importance with reference to diagnosis, and will presently be referred to in that connection.

Certain facts relating to the exfoliation of the false membrane will be found to have important practical bearings. Sooner or later the membrane is thrown off, if the life of the patient be sufficiently prolonged. But before it can be thrown off it must become loosened. The loosening is effected by a suppurative process beneath the false membrane. This process requires a certain period which varies in different cases, but several days must elapse before it is possible for the membrane to be exfoliated. When detached, it is ejected by acts of coughing from the air-passages, and, if the patient be old enough to expectorate, membraniform patches, in greater or less abundance, are found in the expectorated matter, and sometimes branching cylinders are discovered, which are fibrinous casts of the bronchial tubes.

Clinical History.—The symptomatic phenomena in this variety of inflammation, at the outset, are the same as in ordinary subacute laryngitis.

The local and general symptoms are not as marked as in cases of simple acute laryngitis. It is often supposed to be nothing more than a common cold. There is more or less cough, and the cough is hoarse or barking; hoarseness or huskiness of the voice exists, and moderate febrile movement. The symptoms denoting gravity of disease arise from the obstruction due to exudation, in connection with swelling of the glottis and the occurrence of either spasm or paralysis of the laryngeal muscles. One, two, or three days may elapse before the disturbance of respiration is sufficient to create any apprehension. Not infrequently the general symptoms are not sufficient to prevent the child from being up and engaging in play, even after a certain amount of obstruction has taken place. The obstruction due to the exudation and swelling is shown by labored breathing in both acts, and by dilatation of the nostrils. These evidences may be apparent before the obstruction is sufficient to occasion suffering from dyspnœa. The additional obstruction due to laryngeal spasm is shown by the difficulty which occurs in paroxysms or exacerbations. Spasm may be more or less prominent as an element of this form of disease; as a rule, it is far less prominent than in the affections known as false croup. Hence, of all the varieties of so-called croup, this, in its development and early progress, is the least likely to excite alarm.

As the disease advances, the obstruction is increased. The labor of breathing becomes greater, and is attended with manifestations of distressing dyspnœa. The current of inspired air is insufficient for the free expansion of the lungs, as denoted by contraction of the lower part of the chest, with sinking in of the soft parts above the clavicles and sternum in the act of inspiration. The cough becomes stridulous and abortive. The voice or cry is reduced to a husky whisper. The face is congested; an expression of anxiety and distress is marked. More or less febrile movement continues. The sufferings are increased at variable intervals in proportion as the spasmodic element is prominent. If life be prolonged, the cough at length becomes loose, and portions of the false membrane are expectorated from time to time. The obstruction may then gradually decrease and recovery take place. If the disease prove fatal, the mode of dying is by slow apnœa; but not infrequently the suffering from dyspnœa diminishes toward the close of life, and the labor of breathing may be so far lessened as to excite delusive hopes of improvement. Convulsions occasionally occur toward the close of life.

Niemeyer considers as a cause of obstruction, in certain cases, paralysis of the laryngeal muscles, and especially of the posterior crico-arytenoid muscles. As a result of paralysis of these muscles, dilatation of the glottis does not take place in inspiration, and obstruction during the inspiratory act occurs as after section of the recurrent laryngeal nerves in the experiments to illustrate the respiratory movements of the glottis. The author just named states that he has ascertained the fact of immobility of the glottis in cases of the disease by laryngoscopic examination. In so far as the obstruction is due to this cause, it will be manifested in the inspiratory act. A case recently under my observation seemed to exemplify obstruction from this cause. The obstruction was limited chiefly to inspiration, and was accompanied by a laryngeal sound suggestive of a sucking inward of the glottis. In this case the obstruction occurred after the laryngitis had existed for six days, no obstruction having previously existed; and after its occurrence it increased so rapidly that in six or eight hours tracheotomy was required. The age of the patient, three years, rendered the occurrence of œdema of the glottis improbable. Dr. J. Lewis Smith has indicated another important, incidental circumstance which increases

the interference with respiration, namely, the accumulation of muco-pus in the trachea and bronchial tubes, the presence of the false membrane in the larynx, and the feeble expiratory efforts, preventing expectoration. He has observed a case in which this seemed to be the cause of death. The danger from accumulation below the larynx is, of course, incidental to the cases in which bronchitis coexists.[1]

Pathological Character.—The exudation occurs exceptionally in inflammation of a mucous structure. It denotes a peculiar kind of inflammation, and, probably, represents an underlying, special, constitutional, morbid condition. This peculiarity of the inflammation, thus, belongs to it from the beginning. It is not evidence of intensity of the inflammation; on the contrary, the inflammation in this variety of laryngitis is less intense than in the simple acute variety. Simple acute laryngitis, therefore, has no tendency to eventuate in exudation. And in the other affections of the larynx which are commonly embraced under the name croup, the form of disease under consideration, distinguished as true croup, is not liable to supervene.

Causation.—This form of disease is generally met with in young children, but rarely in infantile life. The age, in the great majority of cases, is between two and seven years. The disease, however, may occur at any period from birth to the age of two years, and at any period after seven years. Boys are oftener affected than girls. It occurs oftener in some situations than in others; a cold, humid, changeable climate contributes to its occurrence. Cases occur oftener in the spring and autumnal months than at other portions of the year. Happily, it is everywhere a rare disease, excluding, it will be borne in mind, its occurrence as a complication of diphtheria. It may occur as a primary or a secondary affection. Exclusive of its occurrence in diphtheria, it is sometimes developed in connection with the affection of the pharynx in scarlatina. It occasionally follows measles. The inflammation and exudation, as already stated, very frequently, if not generally, involve more or less of the pharynx. It would seem that the point of departure is, in some cases, the larynx, and in other cases, the pharynx, oftener the latter.[2]

Diagnosis.—Considering the great fatality of this disease, the diagnosis is of great importance with reference to the prognosis and treatment. It is to be discriminated from simple acute laryngitis, from subacute laryngitis with spasm, and from a purely spasmodic laryngeal affection which is presently to be considered. In each of these affections laryngeal spasm is more or less involved, and the character of cough and respiration distinguished as croupal, is chiefly attributable to this element. The spasmodic element is more likely to be prominent, especially at the outset, in the other affections just named, than in this affection; in other words, this, the so-called true croup, presents the croupal phenomena less marked than either of the forms of the so-called false croup. The insidious development of this, the only one of the affections embraced under the name croup which is attended with danger, renders it the only one liable to be overlooked until the disease has progressed so far as to give rise to serious obstruction.

As contrasted with the other affections just named, this slow, insidious

[1] *Vide* Diseases of Infancy and Childhood, by J. Lewis Smith, M.D., etc., 1872.
[2] *Vide* Meigs on Diseases of Children, 3d edition.

development is one of the points involved in the differential diagnosis. In the so-called catarrhal and the spasmodic variety of croup, the croupal phenomena occur suddenly and violently, the attack almost always being in the night. When such an attack occurs without having been preceded by cough, febrile movement, and alteration of the voice, it is almost certain that the affection is not true croup. Alteration of the voice is an important diagnostic feature. This will distinguish it from a purely spasmodic affection, but not from simple laryngitis, either acute or chronic; the voice, however, is affected in a more marked degree in laryngitis with exudation.

The presence of exudation about the epiglottis, and more or less within the pharynx, is a point of great importance in the differential diagnosis. With reference to this point, the observations of Ware are valuable. In this analysis of cases of the several varieties of croup, out of 33 cases of true croup, *i. e.*, laryngitis with exudation, a pharyngeal exudation was observed in all save a single case. On the other hand, of 45 cases of the affections included under the head of false croup, an exudation within the pharynx was sought for and found to be wanting in every case. Of 19 cases observed by Meigs with respect to this point, in all but three an exudation occurred in the pharynx either before or after the development of the laryngitis. In view of these facts, the presence of an exudation within the pharynx, taken in connection with the symptoms which denote laryngitis, renders it extremely probable that exudation exists within the larynx. It is to be borne in mind, however, that the pharyngeal exudation is sometimes wanting, and that its absence in the larynx cannot be inferred from its non-existence in the pharynx, with as much positiveness as its presence in the larynx is to be inferred from its existence in the pharynx.

In the progress of the disease, if it do not destroy life, the discovery of patches of false membrane in the matters expectorated should be considered as the only reliable test of the correctness of the diagnosis. The non-observance of this test has led not infrequently to cases of simple laryngitis being regarded as cases of laryngitis with exudation successfully treated.

With capillary bronchitis this affection need never be confounded. In capillary bronchitis the respirations are very frequent, panting, gasping; in laryngitis with exudation the acts are labored and difficult, and, as a rule, not notably frequent. The embarrassed, noisy breathing, especially during sleep, in cases of enlargement of the tonsils, may, at first, suggest the affection under consideration; but it is readily excluded by the absence of the croupal cough, and of hoarseness.

Prognosis.—The tendency of this disease is to a fatal result. Of twenty-two cases analyzed by Ware, nineteen proved fatal. Even if the affection be limited to the larynx, and uncomplicated, it will destroy life in the great majority of cases, if patients be not saved by surgical interference. The danger is, of course, increased, if the affection extend to the bronchial tubes, and in proportion as it extends towards the smaller tubes. Not unfrequently pneumonitis exists as a complication, and this will, of course, augment the danger. The duration of the disease, in fatal cases, is usually from four to six days. In a small proportion of cases, it kills in less than four days, or life is prolonged beyond six days. If recovery take place, convalescence is reached after a gradual improvement, and is generally slow, the voice remaining more or less affected for a considerable period.

Treatment.—Under the measures of treatment heretofore relied upon, this disease has proved fatal in the vast majority of cases. These measures have been based on the supposition that the exudation depends on the intensity of the inflammation, and, with a view to reduce this intensity, the measures known as antiphlogistic have been vigorously employed. These measures have been employed sufficiently to show that they are not successful; and, if they do not do good, they can hardly fail to do harm. With a view to the proper objects of treatment, it is to be considered that cases are rarely seen prior to the occurrence of exudation, and that the prevention of exudation, therefore, is not the end to which therapeutical measures are to be directed. It is also to be considered that, exudation having taken place, recovery is effected by the separation of the false membrane, and that its separation takes place as a result of a suppurative process beneath it, this process requiring several days. These facts being considered, the rational objects of treatment are to prolong life until the separation of the false membrane can be effected, and to promote the process by which this is effected.

In accordance with these objects, depletion by bloodletting or other means is of more than doubtful propriety. By reducing the strength of the patient, it conflicts with the first object, viz., the prolongation of life. On the contrary, the strength is to be supported, as far as practicable, by concentrated nourishment, and the judicious use of alcoholic stimulants. Emetics, which have heretofore been used excessively in this disease, are to be employed with circumspection in order not to conflict with the first object. They have been given, and frequently repeated, in order to relieve spasm, and it is undoubtedly true, that, for a short period after their operation, the breathing is comparatively easy, but this end may be attained by other measures less objectionable on the score of depressing the powers of life. Another purpose of emetics is to aid in detaching the false membrane. But it is useless to give emetics for this end until the exudation has been loosened by the process of suppuration. Emetics, however, are not to be entirely withheld. In children they compensate for the want of voluntary efforts of expectoration. They may aid in the expulsion of the false membrane when it becomes detached. A fact stated under another head in this chapter is not to be lost sight of, viz., the tolerance of the larynx in young children of an accumulation of mucus sufficient to occasion fatal obstruction. Emetics, then, may be given from time to time, but not too frequently, and the emetic substances used should be those which excite prompt and efficient vomiting without producing prolonged nausea and depression. This will exclude antimony. Ipecacuanha, powdered alum, turpeth mineral, and the sulphate of zinc, are among the articles which may be selected. Of these articles, the turpeth mineral acts promptly and efficiently, without much depression or nausea. My colleague, Prof. Barker, advocates very strongly the employment of this emetic in cases of so-called croup. He considers that, administered at an early period, it modifies the disease, preventing or limiting the production of false membrane. It is to be borne in mind that the accumulation of muco-pus in the trachea and bronchial tubes, in certain cases, furnishes an indication for the use of emetics.

Anodyne remedies are indicated to allay spasm. Opium, however, is to be given with great circumspection. Mercury is admissible on the ground stated under the head of simple acute laryngitis, viz., the objections to its use are not to be taken into account in so dangerous a disease as this, so long as there is any ground to suppose that it will do any good.

In the early part of the disease, cold applications to the neck may be

tried, as in the treatment of simple acute laryngitis. This measure, as in cases of the latter form of laryngeal inflammation, has reference, *first*, to lessening the intensity of the inflammation, that is, to an antiphlogistic effect, and, *second*, to a sedative effect as regards spasm of the laryngeal muscles. To employ cold efficiently, compresses dipped in ice-water may be applied and removed at intervals of a few moments. The continuance of these applications and their repetition are to be determined by the relief which they appear to afford. They should not be persisted in if the patient resolutely resist them, or if they do not seem to give relief. Nemeyer advocates cold applications in this disease; their value was, however, inculcated by Prof. Peaslee, of this city, in 1854.[1] Prof. Peaslee considers the continuous application of cold essential in order to secure its full effect. Prof. J. Lewis Smith employs, instead of compresses dipped in cold water, crushed ice surrounded by oiled silk.

Topical measures of an opposite character have reference to the second object, viz., promotion of the process by which the false membrane is separated. The neck may be enveloped in a poultice or the water dressing, for the same reason that these are deemed useful in phlegmonous inflammation, viz., to hasten suppuration. But the most efficient topical application for this object is the inhalation of steam, and the best method of making this topical application is to charge the atmosphere of the room with as much vapor from boiling water as possible. My colleague, Prof. Sayre, who has been remarkably successful in the management of this disease, attributes more importance to this than to any other remedial measure. He directs the steam to be generated by means of a stove, on which a caldron of boiling water is placed, and the room to be kept at a temperature of 90° Fahr. In a room at this temperature, filled with steam, patients are free from spasm, and breathe with comparative ease. I have observed a case in which the patient passed safely through the disease, the inhalation of steam, after Prof. Sayre's method, being the chief measure relied upon.

Küchenmeister, of Dresden, and Biermer, professor of clinical medicine in the University of Berne, having ascertained that pseudo-membranous exudations are rapidly dissolved in lime-water, considerable masses disappearing in from ten to fifteen minutes, were led to resort to the inhalation of spray from lime-water as a means of removing the false membrane from the larynx and trachea, and they have reported cases in which this treatment was successful.[2] A case has been reported by Dr. H. Ernest Schmid, in which prompt relief was obtained by this measure.[3] Slacking quick-lime is an effective mode of securing this object, and, at the same time, furnishing a warm, pleasant vapor. Breathing pure oxygen from time to time, and diffusing it in abundance in the atmosphere of the room, affords marked relief in dyspnœa. In the case of a child of my late colleague, Prof. Elliot, steam from boiling water, the lime vapor produced by slacking a barrel or more daily of quick-lime in the room, the inhalation of oxygen which the child soon desired from the relief derived from it, and keeping the atmosphere of the room charged with oxygen from a continuous stream of the gas, were the only measures employed, in addition to alimentation and a little alcoholic stimulant, excepting an emetic of turpeth mineral when the symptoms and signs denoted loosening of the laryngeal false membrane. The child passed through the disease not only safely, but without great suffering.

[2] *Vide* Am. Jour. of Med. Sciences, Oct. 1865, p. 518.
[3] *Vide* N. Y. Med. Record, April 15, 1867.

Dr. R. R. Livingston, of Plattsmouth, Nebraska, has reported a case in which the inhalation of ether appeared to effect a speedy separation of the false membrane.[1] The inhalation of vapor from lime-water containing lactic acid has been employed with success as a solvent of the false membrane.[2]

The topical application of a strong solution of the nitrate of silver was advocated by Dr. Green. The introduction of the sponge probang into the larynx of the child is difficult, owing to the small size of the glottis, and, frequently, the want of co-operation on the part of the patient; yet it may be effected. I have witnessed a recovery in a case in which this was the chief measure relied upon. The applications were made twice daily. When the false membrane is loosened, the introduction of the sponge may be useful mechanically, detaching the membrane and pushing it below the glottis, thus leading to its expectoration.

Lastly, the propriety of tracheotomy, in cases of this affection, is to be considered. The subject has been much discussed of late years, and opinions in Great Britain and in this country are divided. Introduced by Bretonneau, and finding an ardent advocate both by practice and precept in Trousseau, the propriety of the operation appears to be generally conceded in France. For statistics bearing on this subject the reader is referred to treatises on the diseases of children, and articles in medical periodicals.[3] The propriety of the operation hinges, not on the number of cases in which it has proved successful, but on the answer to the question whether any lives are saved by it. Now, it cannot be doubted that patients with this disease have been snatched from impending death by this operation. It is, therefore, not only justifiable, but the practitioner is bound, if possible, not to allow patients to die from suffocation for the want of its performance. Of course, the duty of resorting to the operation is the more imperative the greater the probability of its success; and a fair examination of statistics will show that not a small proportion of those who would otherwise die may be rescued by it.

The success of tracheotomy must depend much on its timely performance. Its failure in many cases is attributable to its having been too long deferred, but it has proved successful repeatedly as a *dernier ressort* under the most unpromising circumstances. So soon as the persisting obstruction, that is, the obstruction due to the exudation, associated perhaps with paralysis of the dilating muscles of the glottis, compromises respiration sufficiently to render it probable that the patient's life will not be prolonged until the separation of the false membrane can take place, the operation is called for. Its success, doubtless, depends much on the manner of its performance, and the subsequent management. On these points the reader will do well to study the instructions of Trousseau. My colleague, Professor Sayre, attaches great importance, after the operation, to an atmosphere heated to 90° and charged with steam.

Dr. William Jenner has pointed out an objection to a premature performance of tracheotomy, namely, the effect of the operation on the ability to cough. In an efficient act of coughing, first, a deep inspiration is taken and the glottis closes; then by means of forcibly expiratory efforts the

[2] For review of experiments by Brichteau and Adrian, *vide* Am. Jour. of Med. Sciences, Oct. 1868.

[3] *Vide* article in the New York Journal of Medicine, Jan. 1860, by A. L. Voss, M.D., in which the writer gives the results in 1249 cases, the recoveries being 294. Also, valuable statistics, etc., by Prof. Jacobi, who has had a large experience. Am. Journ. of Obstetrics, New York, May, 1868.

current of expired air, dislodging from the bronchial tubes their contents, carries them into the trachea, and, the glottis suddenly opening, expectoration is effected. Now, with a tube in the trachea an efficient act of coughing cannot take place; hence, there is a greater liability to accumulation in the bronchial tubes than if tracheotomy had not been performed. The danger from this effect of the operation thus relates to the bronchial tubes in the cases in which bronchitis is associated with the laryngitis.

If the operation prove unsuccessful, it diminishes greatly the suffering from obstruction, and is fully justifiable with a view to euthanasia.

Œdema of the Glottis.

This name denotes a serous or dropsical effusion in the areolar tissue beneath the mucous membrane above the vocal cords. It is for convenience used, however, in a more comprehensive sense, embracing cases in which inflammatory products are deposited in the same situation. In the latter case, the condition is incidental to laryngitis. As a true œdema, it is an occasional accident, in cases of pharyngitis and tonsillitis. I have met with an instance in each of these connections. Its occurrence is due to the inflammation of the mucous membrane in proximity to the seat of the effusion, and it is analogous to the subcutaneous œdema which accompanies inflammation of the skin in situations where the areolar tissue beneath is abundant and lax, as, for examples, around the eyes and on the penis—the collateral œdema of Virchow. The affection occurs in cases of typhus and typhoid fever, in epidemic erysipelas, in albuminuria, and various other diseases. Its occurrence in these pathological connections is extremely rare.[1] As an idiopathic affection it is certainly one of the rarest diseases. It is important to add that it may occur as the first and only dropsical affection connected with disease of the kidneys. Its gravity, and the necessity of prompt and efficient interference, render it vastly important to appreciate the pathological condition, and recognize its existence.

The situation of the effusion is to be borne in mind. It takes place in the areolar tissue, which, in the adult, is abundant and loose between the vocal cords and epiglottis on the top of the glottis. The accumulation of liquid in this situation may give rise to tumors as large as, or even larger than, a pigeon's egg, which, lying upon the glottis, are sucked inward with the inspiratory act, and thus occasion obstruction in this act. The current of air in expiration separates and pushes the tumors upward, so that in cases of œdema without laryngitis there is little or no obstruction in the expiratory act. The œdema usually exists on both sides, but it is sometimes limited to one side. The occurrence of the œdema may be sudden, and life be destroyed in a few hours, or even minutes.[2] In a case occurring in connection with mild pharyngitis, the suffering from obstruction was developed during the night, and the patient, leaving his apartment to seek for aid, fell upon the floor and died before any assistance could be rendered. In the case in which it occurred in connection with tonsillitis, the patient was left to sleep in an apartment by himself, there

[1] In an article on this subject by Dr. Thomas Addis Emmet (*American Journal of the Medical Sciences*, July, 1856), Dr. E. states that only seven cases of simple œdema occurred in one thousand nine hundred and thirty-one cases of typhus, during a service of five years in the New York State Emigrant Hospital at Ward's Island.

[2] A case is reported in *Guy's Hospital Reports*, April, 1855, which terminated fatally within five minutes after difficulty from obstruction was experienced.

being no difficulty of breathing, and, in the night-time, a relative in an adjoining room was awakened by his noisy breathing. He was found to be unconscious, and, although medical aid was promptly called, and the trachea opened without delay, the operation was too late to prevent a fatal result.

Difficulty of breathing, due to obstruction at the glottis, is a prominent symptom. This is associated with a sense of a foreign substance at the seat of the obstruction, and a strong disposition to hawk and swallow. The diagnostic point relating to the difficulty of breathing is, the inspiratory act is alone, or chiefly, obstructed, the act of expiration being free. The inspiration is arrested before it is completed, being, as it were, suddenly cut short, and both the inspiration and expiration are accompanied by marked stridor. If laryngitis do not coexist, the voice is devoid of hoarseness or huskiness. This will serve at once to exclude laryngitis. I have met with a case, ending fatally, in which there was no hoarseness nor huskiness of the voice, and no appearance of laryngitis after death. But the diagnosis may frequently be made positive by means of the touch. With the forefinger introduced into the mouth, carried to the base of the tongue, and applied below the epiglottis, the œdematous tumors may be distinctly felt. This diagnostic test, enunciated by Tullier in a thesis submitted to the Faculty of Medicine, in Paris, in 1815, appears to have been lost sight of until attention was called to its appearance a few years since, by Dr. Gurdon Buck, of New York.

Statistics show a large fatality in cases of œdema of the glottis. Bayle found that in 17 cases only 1 recovery took place. Of 40 cases collected by Valleix, 31 were fatal. Of 168 cases collected by Sestier, 127 died. With a correct appreciation of the pathological condition, a prompt recognition of it, and timely surgical interference, many, if not most, patients may be saved. It is fair to attribute the large proportion of fatal cases heretofore either to an imperfect knowledge of the affection, error or doubt in the diagnosis, or want of promptness in resorting to efficient interference.

The affection tends to destroy life quickly by apnœa. The object of treatment is to prevent suffocation, and if the obstruction be sufficient to occasion great labor of breathing, lividity, etc., there is no time to be lost in fruitless efforts to obtain relief by medication. The larynx or trachea must be opened, or the method of scarification, as practised by Dr. Gurdon Buck, must be resorted to. Dr. Buck's method consists in introducing a curved bistoury, properly guarded, into the mouth, carrying it below the epiglottis guided by the left index-finger, and scarifying on both sides, so as to give exit to the effused liquid. The scarification may be repeated if required.[1]

My personal observation of Dr. Buck's operation is based on a single case, in which it was employed by a surgical colleague at a moment's notice, and without the advantage of a prior acquaintance with it. The difficulty in the way of its performance is greater than might be supposed without a trial of it. The increase of the suffering for want of breath caused by introducing the fingers into the mouth, the movements of the larynx incident to the labored breathing, and the acts of vomiting which are excited, render it not easy to deliberately scarify the œdematous parts. In the case referred to, the result was unfortunate. The tumors were not sufficiently scarified, but wounds were made which led to hemorrhage and the flow of blood into the air-tubes. Tracheotomy was subsequently per-

[1] *Vide* Trans. Am. Med. Association, vols. i. and iv. Several cases successfully treated by this method are reported by Dr. Buck.

formed, but too late to save the patient. The case is referred to in order to enforce the importance of being prepared to meet with more difficulty than might be anticipated. Without assuming to adjudicate in a matter which is purely surgical, I am disposed to think that the simpler, as well as the more effectual, operation is to open the larynx or trachea. Niemeyer states that in some cases the finger-nail will suffice to open the œdematous tumors.

A case at Bellevue Hospital exemplified the importance of opening the trachea before the obstruction threatens immediate death. A patient was suffering considerably from difficulty of breathing, but it was decided not sufficiently to require tracheotomy. The House Physician, however, made every preparation to perform the operation at an instant's notice. Suddenly the difficulty of breathing increased, and the physician was in a few moments at the bedside, but too late to save the patient. The liability to a very rapid increase of obstruction proving quickly fatal, is to be considered in deciding upon the propriety of opening the trachea. The operation may be advisable, as a precautionary measure, even if life be not at the moment threatened, when the practitioner cannot remain with or near the patient until danger is passed.

Œdema of the glottis very rarely, if ever, occurs in infancy or childhood, the reason probably being that the areolar tissue at the situation where the œdema occurs is less abundant and loose in young subjects than after puberty.

Spasm of the Glottis.

Spasm of the glottis is an important element in most of the affections of the larynx which have been considered. To this element are attributable the croupal cough and the paroxysms or exacerbations of dyspnœa in simple acute, and subacute laryngitis in children, and in larygitis with exudation. But spasm of the glottis occurs as a functional affection, that is, irrespective of inflammation or lesions within the larynx. It is an element of several of the functional affections of the nervous system (neuroses) to be hereafter considered, namely, in hysteria, epilepsy and epileptoid convulsions and tetanus. Occurring independently of these connections, it may be reckoned among the functional affections of the larynx.

Spasm occurs in young children, affecting the respiration without inducing cough. This is the pathological condition when infants are said to have fits of "holding the breath." Respiration is arrested until the face becomes congested and livid, and, when the spasm relaxes, the inspiration may be sonorous, as in pertussis. In some children these paroxysms occur more or less frequently. They are sometimes accompanied by carpo-pedal spasm. Convulsions may occur. Death may take place in a prolonged paroxysm, or in consequence of repeated paroxysms in rapid succession. I have known an instance of this kind. The affection is commonly known as *laryngismus stridulus*. From a supposed connection with persisting enlargement of the thymus gland after birth, it has been called *thymic asthma*.

The affection is purely neurotic. It involves a peculiar susceptibility to spasm in the laryngeal muscles. This susceptibility may be incident to a certain period, as during weaning or dentition, but, in some cases, it appears to be an idiosyncrasy of infantile life. When the predisposition exists, paroxysms are liable to be excited by various causes, acting physically and mentally. This susceptibility is sometimes observed in the different children of the same family, a fact in confirmation of its innateness.

During a paroxysm, it is customary to employ means to produce a strong impression on the surface, as slapping the back or sprinkling cold water on the face. The treatment otherwise involves the removal of all local causes of irritation, such as the distension of the gums and the retention of fecal matter, avoidance of causes inducing mental excitement, and measures to invigorate the system.

Spasms of the glottis occurring in children over two years of age, accompanied by laryngeal irritation and cough, is a frequent affection, known as *spasmodic croup*. A child is suddenly attacked during the night, having, perhaps, gone to bed apparently in perfect health. The breathing is labored and sonorous, the cough presents, in a marked degree, the shrill, ringing, croupal character. Great alarm is produced, and the physician is sent for in urgent haste. The surface of the body is cool; the pulse is small and perhaps not accelerated; the voice or cry is not hoarse nor husky as in laryngitis: the affection, in short, is purely spasmodic. It is unattended with danger. When the violent symptoms are relieved, the respiration is found to be unobstructed. There is no liability to its eventuation in so-called true croup, that is, to laryngitis with exudation. It is to be discriminated from the latter affection. The points involved in this discrimination are as follows: the abruptness of the attack, which is not preceded by symptoms denoting laryngitis; the violence of the attack, in this respect differing from so-called true croup; the absence of hoarseness or huskiness of the voice, of febrile movement, and of exudation in the larynx; and, finally, the speedy and complete relief. The paroxysms may return for two or more successive nights.

The treatment consists of a mild emetic, if there be reason to suppose that the stomach is overloaded, a hot foot-bath, and warm fomentations to the neck. These measures are uniformly successful. The treatment of these cases is sometimes needlessly active, under the impression that a serious affection is threatened; and practitioners are apt to congratulate themselves and the friends of the patient on their success in preventing true croup.

Spasm of the glottis may occur as a functional affection in the adult. It is occasionally incidental to hysteria, and may simulate, as regards some of the symptoms, laryngitis, or œdema of the glottis. The diagnostic points are as follows: The coexistence of hysterical phenomena; the absence of huskiness or hoarseness of the voice; intermittency of the difficulty of breathing; the speedy relief obtained by anodyne remedies, and the sudden development of the affection. I have been consulted in several cases in which spasm of the glottis occurred in male adults without any evidence of disease within the larynx or intra-thoracic disease.

The measures of treatment are anodyne or antispasmodic remedies for immediate relief, and afterward those indicated by the general condition, and which are employed in analogous nervous affections.

Spasm of the glottis may be occasioned by irritation of the recurrent laryngeal nerve from the pressure of a tumor or other causes. It is one of the symptoms of aortic aneurism, and, occurring in a person over forty years of age, should always excite a suspicion of aneurism. I have reported a case of aortic aneurism in which the life of the patient was destroyed by frequently recurring paroxysms of laryngeal spasm.[1]

[1] American Medical Times, 1864.

Nervous Cough.

The term nervous cough is used to designate a neuropathic disorder characterized by a dry, peculiar cough occurring without laryngitis, bronchitis, or any pulmonary affection. It may be noticed with propriety among laryngeal affections, inasmuch as the distinctive character of the cough relates to the larynx. In most of the cases which I have seen, the cough has had a peculiar barking tone; and the pitch has been low, showing that the glottis was dilated at the instant of coughing. In some cases, however, the tone is shrill, and the quality of sound croupal, showing spasm of the glottis. In a case recently under observation, the cough consisted of a single, short, hoarse bark, often repeated several times in a minute. The cough is sometimes in paroxysms, having a resemblance to those of whooping-cough. The peculiar sound of the cough, together with its frequent recurrence, and sometimes its violence, renders it distressing to those whose sympathies are excited, and annoying to others.

This disorder rarely, if ever, occurs in males. It is often associated with more or less of the symptoms embraced under the name hysteria. The cough has been called *tussis hysterica*, and it is usually included, by medical writers, among the diversified hysterical manifestations. It occurs chiefly in young chlorotic females. I have known it to occur before the age of puberty. It is apt to persist for a considerable period.

The diagnosis is to be based on the peculiarity of the cough; its dryness, except that the acts of coughing, if frequent and violent, may occasion some mucous expectoration, and the negative result of a careful physical exploration of the chest. The diagnosis is strengthened, on the one hand, by the coexistence of anæmia, and of hysterical phenomena, and, on the other hand, by the absence of rational symptoms pointing to tuberculosis.

The indications for treatment relate to anæmia, if it exist, and to other morbid conditions affecting the nervous system. Tonic remedies, a nutritious diet, out-of-door life, and, in a word, invigorating measures are indicated. In addition to chalybeates, quinia, small doses of strychnia, and the preparations of zinc may be mentioned as appropriate remedies. Hygienic measures, however, are of the first importance. A change of climate is sometimes advisable, if other measures fail. A sea-voyage proved effective, in a case under my observation, after a long persistence of the cough in spite of various measures of treatment. As palliatives for the cough, antispasmodic remedies may be prescribed, but opiates are not advisable.

Nervous Aphonia.

Loss of voice, or aphonia, is incidental to the several varieties of laryngitis which have been considered. But it occurs when not dependent either on inflammation or lesions within the larynx; in other words, as a functional affection. It is then known as nervous aphonia. The loss of voice is due to paralysis affecting the nerve of phonation, viz., the spinal accessory. The affection is limited to the voluntary movements of the laryngeal muscles, the reflex movements involved in respiration being unaffected.

This form of aphonia is met with not infrequently in females, and is usually associated with more or less of the phenomena embraced under the name hysteria. As a purely neurotic affection, that is, not dependent on any lesion of the nervous system, it must be extremely rare in the male sex. A distinction is to be made between loss of voice and loss of speech,

the latter occurring in a certain proportion of the cases of hemiplegia, and dependent, not on the loss of power to produce vocal sounds, but on either a defect in articulation or the loss of memory of words. Aphonia occurs from pressure on the recurrent laryngeal nerve of an aneurismal or other tumor, and the loss of voice should direct attention to this as a possible or probable cause.

The diagnosis of nervous aphonia may be made by attention to the character of the whispered voice; the patient speaks in a pure, soft whisper, without effort. On the contrary, if the aphonia be due to laryngitis, the whisper is stridulous or husky and labored. Moreover, in aphonia due to laryngitis there is more or less cough and expectoration, symptoms generally absent in nervous aphonia. As the question is usually to decide between nervous aphonia and chronic laryngitis, and as the latter affection is generally associated with pulmonary tuberculosis, the absence of the symptoms and signs of the latter disease will serve to confirm the diagnosis. Examination with the laryngoscope will corroborate the diagnosis by showing that the larynx is free from lesions; and the absence or the incompleteness of movements of the glottis when an effort to speak is made may be ascertained by inspection.

Inspection with the laryngoscope shows that the paralysis may be bilateral or unilateral; and that the different muscles, namely, the adductors and abductors, the tensors and the laxors, may be affected separately. Unilateral paralysis, of course, points to some cause affecting the accessory nerve on one side only, and it is especially suggestive of an aneurismal tumor pressing upon one of the recurrent laryngeal nerves.

If the aphonia be purely neurotic, in other words, involving no lesion of the nervous centres, nor pressure on either the par vagum or the recurrent laryngeal nerve, recovery may be expected after a duration of the affection varying much in different cases. The voice is sometimes restored instantaneously and unexpectedly. I have met with cases in which repeated attacks had occurred.

Treatment in these cases should be directed to the general condition; tonic remedies and invigorating hygienic measures are indicated. Moderate counter-irritation may be useful. Electrization of the laryngeal muscles has been found signally useful. Both the induced and the direct current are used with success. The recovery of the voice sometimes follows a single application, or even a single electrical shock; but, in some cases, the treatment, to be successful, must be continued for several weeks. In some of the cases in which electricity at once effects a cure, there is reason to think that the success is due to a moral influence. Dr. Henry K. Oliver has found the following method of manipulation successful in several cases: The wings of the thyroid cartilage, in their posterior and upper part, are to be compressed by the thumb and forefinger, the patient being instructed, at the same time, to make an effort to speak. In his cases a feeble voice sound, after a little time, was produced, and this was followed shortly by the full restoration of the voice. He explains the effect by supposing that the approximation of the vocal cords from the pressure, as it were, "starts the machinery of the vocal apparatus."[1] This method is suited only to cases of bilateral paralysis of the adductors. It may reasonably be conjectured that the efficacy of the method is measurably, at least, dependent on a psychical effect.

After a partial restoration of the voice, occurring either under general treatment only, or following local measures, complete recovery may be

[1] *Vide* Am. Jour. of Med. Sciences, No. for April, 1870.

expected by systematic efforts of speech, in the same way as the control of the will over other paralyzed muscles is effected by means of persistent voluntary exercise. Commencing with the vowels most easily spoken, the practice should extend to those more difficult of utterance, then to consonants and words of one syllable, and finally to sentences. A case has been related to me in which aphonia had existed for several years, and the patient, a female, was promptly cured by taking a quantity of spirit sufficient to produce inebriation. The patient's habits were temperate, and this was advised as a curative measure by her physician, who had heard of a cure having been thus effected in another case.

Morbid Growths.

The laryngeal mucous membrane, especially at the vocal cords, is sometimes the seat of morbid growths in the form of warty vegetations, or tumors, which are generally epithelial, but sometimes fibro-cellular, either sessile or pedunculated, the latter called polypi; these occasion inconvenience, suffering, and death, by producing obstruction. Surgical interference becomes necessary when the obstruction is sufficient to endanger life. A tube may be worn in the trachea for an indefinite period. In a case in which a permanent artificial opening becomes necessary, it may be a question whether a large fistulous orifice might not be established, rendering the tracheal tube unnecessary. As bearing on this question, the following case is of interest. A patient, aged about forty, admitted into one of my wards in Bellevue Hospital, suffering from the effects of a debauch, had a fistulous orifice in the anterior portion of the trachea large enough to admit the end of the forefinger. This fistula followed a wound received in a fracas, and had existed for seventeen years. It occasioned little or no inconvenience in respiration. There were no symptoms of inflammation or irritation of the trachea or bronchial tubes, and he was entirely free from pulmonary disease; the only inconvenience which it occasioned was in speaking. In order to direct a current of air through the glottis sufficiently for the production of the voice, he was accustomed to approximate the chin to the sternum, and in this way he was able to close the fistula. The patient died in hospital of delirium tremens, and the larynx is preserved in the hospital museum. Cancer seated primarily in the larynx is rare; the disease, in the cases in which this part becomes affected by it, generally originating in the œsophagus or in the neck exterior to the larynx. The laryngoscope has proved to be of great practical value in determining the existence, situation, size, and character of morbid growths within the larynx, and in facilitating surgical operations for their removal through the laryngeal aperture.

CHAPTER X.

PULMONARY TUBERCULOSIS.

Definition and Scope of the Term Pulmonary Tuberculosis—Anatomical Characters—Clinical History—Pathological Character—Causation.

CERTAIN changes in nomenclature recently proposed, and to some extent adopted, render necessary an explanation of what is meant by the term *pulmonary tuberculosis*. As stated in the first part of this work, some pathologists, taking as a point of departure histological observations, propose to restrict the name tubercle to the bodies known as gray tubercles, semi-transparent granulations, etc. (*vide* page 36); and to apply the term pneumonia to the affection characterized by the presence of the product commonly known as yellow or infiltrated tubercle; and in order to distinguish the latter from other forms of pneumonitis, various adjectives have been proposed, such as tuberculous, lobular, disseminated, cheesy, catarrhal, etc. The term pulmonary tuberculosis has hitherto embraced the affection to which has been of late applied the name pneumonia with these various prefixes. I shall continue in the fourth edition of this work, as in the previous editions, to use the term in the comprehensive sense just stated. Without any qualifying prefix, it is considered as denoting a chronic affection. A rare variety of tuberculous disease is distinguished as *acute pulmonary tuberculosis*. This will be noticed after having considered the common form of tuberculous disease. Popularly, the affection is known as consumption, or, sometimes, *the decline*, names which are significant in view of the wasting of the body which attends its march, but yet not distinctive, inasmuch as progressive emaciation belongs to the history of other affections. The name *phthisis*, or *phthisis pulmonalis*, has the same significance, that is, expressing wasting or emaciation, and is open to the same objection. Of the diseases which afflict the human family, this is one of the most important, prevailing, more or less, in every quarter of the globe, and occasioning, exclusive of those which prevail epidemically or endemically, a larger proportion of deaths than any other disease. Statistics show that of the population of England, France, Germany, and Russia, amounting to two hundred and thirty millions, the annual deaths from this disease are eight hundred and sixty-nine thousand; and that of the people inhabiting the globe, amounting to nine hundred and sixty-eight millions, three millions die each year with this disease.[1]

Anatomical Characters.—For an account of the morbid products known as the gray and the yellow tubercle, the reader is referred to Part First of this work (*vide* p. 36). The differential characters belonging to these two products are there given, and certain questions, concerning the relationship existing between them, briefly considered. The pathological interest of these questions is greater than their apparent practical importance. In general, gray tubercles, and the so-called yellow tuberculous infiltration (tuberculous pneumonia), are associated, the relative proportion

[1] Dr. Schnepp, in Archives de Médicine. Juin, 1865.

of each, as regards quantity, varying much in different cases. In chronic pulmonary tuberculosis, the latter product, that is, the tuberculous infiltration, is especially important, for it is this which, from its amount, the changes which it undergoes, and the destruction of pulmonary tissue to which it leads, is the chief source of danger so far as concerns the local pulmonary conditions.

As regards the amount of morbid products, pulmonary tuberculosis varies much at the outset, in different cases. Different cases also differ much as regards their progressive accumulation. In some cases an increase goes on steadily, that is, without intermission; in other cases, after a certain amount, there is no further increase for an indefinite period. Not infrequently products occur, as it were, in successive crops, at epochs more or less remote. In some cases they are disseminated in nodules, or tubercles, of small or moderate size. In other cases the nodules, at first isolated, become aggregated by accretion, multiplication, and coalescence, forming irregular masses of considerable size.

They are situated first at or near the apex of one lung, in the vast majority of cases, and in the progress of the affection they extend downwards, more or less, towards the base; but, sooner or later, they occur at or near the apex of the other lung, thence extending downward. Different collections of cases analyzed in order to determine whether the right or left lung is most liable to be first affected, have furnished discrepant results, showing that there is no fixed law with respect to this point. Exceptionally, the affection commences at the base and extends upward. These exceptional cases are exceedingly rare; of 4,530 cases analyzed with reference to this point by Pollock, the affection commenced at the base in sixy-four.

In the early period of the disease, there is a marked difference in different cases in respect of the latency of the affection. In some cases the tuberculous products, although considerable, occasion but little local disturbance; in other cases they cause irritation and inflammation in the surrounding tissues. Circumscribed bronchitis occurs sooner or later, and is more or less marked. Inflammation of the parenchyma, extending over a limited number of lobules (circumscribed pneumonitis), is incidental to the deposit in some cases, increasing, for a time, the degree and extent of solidification, and sometimes contributing to the breaking down of the pulmonary structures. The parenchymatous inflammation now referred to does not differ from ordinary pneumonitis. As in the latter, the exudation within the air-cells may be absorbed and sometimes disappears rapidly. It is, of course, to be understood that the yellow tuberculous product to which some pathologists of late apply the name chronic pneumonia is not now referred to. Chronic or interstitial pneumonitis is also a frequent contingent affection, increasing, more or less in degree and extent, the solidification of lung. Tuberculous collections are not infrequently surrounded with dense tissue, or, as it were, encysted, as a result of interstitial inflammation. A result of the latter is sometimes the production of cavities by dilatation of the bronchial tubes. Attacks of circumscribed pleuritis occur almost invariably. They may occur early in the history of the affection. They may recur at variable periods, leading to the exudation of lymph, without liquid effusion, and to adhesion of the pleural surfaces, by means of intervening organized membrane. The occurrence of successive attacks of dry circumscribed pleuritis explains the firm atachment, which is generally found in examinations after death, of the pleuritic surfaces over portions of the lungs corresponding to the sites of the tuberculous collections. Diminished volume of the affected portions of the lungs due to collapse of pulmonary lobules and interstitial pneumonitis are

incidental to the affection, even before softening of the tuberculous collections has taken place. Emphysema of more or less of the lobules in proximity to the tuberculous collections, is another morbid condition not infrequently observed.

Softening, the discharge of liquefied tubercle by ulceration into the bronchial tubes, and its expectoration, take place after a period which varies much in different cases. The affection has now advanced to the formation of cavities. When the tuberculous collections first formed have in this way been removed, those of a subsequent date are undergoing softening, and at length are, in like manner, removed. Hence, as the affection progresses, new cavities are formed. In examinations after death, cases differ much as regards the number and size of the tuberculous cavities. The greater part of the upper lobe of one lung, and sometimes of both lungs, may be converted into a single cavity or a series of cavities. These cavities are generally irregular in form, with ridges of pulmonary tissue and depressions, and hence they are distinguished as anfractuous. Not infrequently they are traversed by bands of pulmonary tissue, containing blood-vessels, and the rupture of these is the source of the hemorrhage which occurs in certain cases. The cavities become lined with a membrane which is thick and dense in proportion to their age. The destruction of lung is, of course, in proportion to the number and size of the cavities, and their formation leads to a still further reduction of the volume of the portions of the lung in which they are seated. Exceptionally, the liquefied tubercle is evacuated by ulceration through the pleura, into the pleural sac, giving rise to pleuritis with effusion, and allowing the entrance of air, thus causing pneumo-hydrothorax. The adhesions resulting from the successive attacks of dry circumscribed pleuritis are conservative as regards protecting against this accident which occurs in only a small proportion of cases.

A simple and convenient division of this affection into stages is based on the marked difference, as regards the anatomical characters, before and after the formation of cavities. The first stage embraces the period during which the tuberculous products accumulate and soften, up to the evacuation in a liquefied state. The second stage extends from the time when cavities are formed to the termination of the affection. A stage of softening, distinct, on the one hand, from the period during which the products are solid or semi-solid, formerly called crude tubercle, and, on the other hand, from the cavernous stage, is superfluous, for the existence of such a stage cannot be predicated with any degree of certainty on either symptoms or signs. As regards the two stages, viz., before and after excavation, it is to be borne in mind that frequently, if not generally, both are represented at the same time in different portions of the lungs. After cavities have been formed in certain portions, more recent collections in other portions are still either crude or undergoing the process of softening.

In this division into two stages, it is assumed that the affection goes on to the formation of cavities. This, unhappily, is the rule; yet, exceptions to the rule are not very infrequent. If the tuberculous products be disposed in small, disseminated nodules or tubercles, they may be absorbed. In some cases the animal constituents of the deposit are absorbed, leaving the mineral portion, and the latter become hard calcareous bodies which may remain imbedded in the lung, or, ulcerating into the bronchial tubes, they are expectorated. In these modes a cure of the local affection takes place in a certain proportion of cases. But a cure may also take place after the affection has gone on to the second stage. It is well ascertained that cavities, even of considerable size, may gradually contract, and, at length, perfectly cicatrize. In some cases in which cicatrization does not

take place, cavities become lined with a non-secreting membrane, and they may remain nearly innocuous for an indefinite period.

Some writers have recognized, as a stage of the disease, a period anterior to the tuberculous deposit, which has been called the pre-tuberculous stage. It has been supposed that such a stage may be determinable by symptoms and signs. That both a general and local morbid condition precede the deposit can hardly be doubted, but that anatomical changes take place, which are represented by symptomatic phenomena, and which may be appreciated by physical exploration, cannot be considered as established by clinical observation.

Clinical History.—In sketching the clinical history of this affection, the symptoms attending the development and the first stage, will, in the first place, claim attention.

The affection is often remarkably insidious in its development. In a certain proportion of cases the pulmonary symptoms are preceded, for several weeks or months, by deteriorated general health, as denoted by loss of weight, impaired muscular strength, and a pallid aspect. These premonitions, however, are not constant, and, if they exist, are rarely sufficiently marked to excite the attention of the patient or others. It has been stated by James Clark, Bennett, Tweedy, Todd, and others, that certain dyspeptic ailments are apt to precede the development of the affection. If this be so, the ailments are not, as a rule, of a striking character. In a pretty large proportion of cases, the pulmonary symptoms which may be considered as denoting the tuberculous affection, are neither preceded nor accompanied by ailments of any description which lead the patient to suspect the existence of any disease. In the majority of cases, when the patient first comes under the cognizance of the physician, the previous history renders it probable that the affection has existed for several weeks, or, perhaps, months.

Of the pulmonary symptoms, the first which occurs is cough. Unless the affection be developed coincidently with an attack of bronchitis, which is not common, the cough is, at first and for some time, slight, dry, hacking, and perhaps excites little or no attention. Occasionally, however, it is, from the outset, a prominent symptom. The expectoration, for some time wanting, is at first small, and consists of foamy or glairy mucus. It progressively increases, becoming gradually more or less abundant, and at length solid and opaque. These symptoms proceed from irritation and circumscribed bronchitis. Hæmoptysis frequently takes place shortly after the occurrence of cough and expectoration. In some cases it precedes these symptoms. It is often the event which first excites any apprehension of serious disease, and leads the patient to seek medical advice. If cough and expectoration have existed for some time prior to this event, the patient had not heeded them, thinking they were due to a slight cold, and that they would shortly disappear.

Pain in the chest does not belong to the tuberculous affection *per se*. Pain, however, is apt to occur, at times, more or less frequently, during the first stage of the disease, being due to the circumscribed pleuritis to which reference has been made. The pain is sharp, lancinating or stitch-like, referred to the summit of the chest, and frequently shooting beneath the scapula. It varies at different times and in different cases in severity, being rarely sufficient to keep the patient in bed or even within doors, and it may continue for one, two, or three days. In the progress of the disease, the pain in these attacks is referred successively to both sides of the chest, and it may be most severe and frequent on the side in which the

amount of the tuberculous affection is least. These attacks are frequently considered by patients to be rheumatic or neuralgic. They possess considerable diagnostic significance, but they are of very little importance as indicating gravity or progress of the disease. Intercostal neuralgia occasionally occurs in tuberculous patients, and is to be distinguished by the diagnostic points which have been presented in treating of that affection.[1] The respirations are usually increased in frequency, and the increase, other things being equal, is in proportion to the amount of the tuberculous products. This symptom may not attract the notice of the patient. It is apparent especially on exercise. It is rarely the case that suffering from dyspnœa is experienced, and to ascertain the existence of this symptom, it may be necessary for the physician to observe for himself, and not trust to the statement of the patient. Even when, owing to the amount of tuberculous products, and the rapidity with which they have been developed, lividity is marked, dyspnœa is not always complained of.

Among other than pulmonary symptoms, the condition of the circulation, as represented by the pulse, holds an important place. During the first stage, more or less acceleration of the pulse is the rule, and this acceleration, although not great, is an important symptom in a diagnostic point of view. The amount of acceleration differs much in different cases. In general, the frequency of the pulse is in proportion to the activity of the tuberculous affection. If the pulse be habitually frequent, the disease will be likely to be rapidly progressive. A certain proportion of cases are characterized by frequency of the pulse, which is also quick, vibratory, and compressible, qualities denoting morbid activity, but diminished power, of the contractions of the left ventricle. In these cases the career of the disease is apt to be short, the products progressively accumulating and running rapidly through their changes.

The temperature, as determined by the thermometer in the axilla, as a rule, is more or less raised in proportion as the tuberculosis is progressive. The thermometer is thus useful by aiding in the diagnosis of tuberculous disease, and if the diagnosis be not doubtful, by affording evidence of the disease being progressive or otherwise. When it is a question as to the diagnosis, increase of animal heat is evidence for, and absence of any increase of heat is evidence against, the existence of tuberculosis. In well-marked cases of tuberculosis the amount of increase of heat is a measure of the activity of the disease, whereas a normal temperature denotes that the disease is non-progressive.

Daily febrile exacerbations, commonly called hectic fever, may occur in the first stage. Toward evening the acceleration of the pulse is increased, with increased heat of skin, and sometimes a marked sensation of burning in the soles and palms; the cheeks may present a circumscribed flush, and after some hours the exacerbation goes off with perspiration. The exacerbation is sometimes preceded by a chill. Chills also occur without being followed by notable febrile movement. They may be pronounced and accompanied by some rigor, or they are slight and transient, consisting, in some cases, of occasional shiverings or a sensation as if water were trickling down the back. Well-marked chills, followed by increased heat and perspiration, may occur with such regularity that the patient is supposed to be affected with intermittent fever, and, under these circumstances, if the pulmonary symptoms be slight, the affection of the lungs may be for some time overlooked. I suppose there are few physicians of much experience in situations where they are liable to meet with intermittent fever,

[1] *Vide* page 202.

who cannot recall cases in which this error of diagnosis has been made. Febrile movement of limited duration may be due to an intercurrent circumscribed pneumonitis which is simple, that is, not tuberculous in character.

As regards appetite and digestion, there is much diversity in different cases. In general, the desire for food is diminished, and the ability to digest food impaired. In some cases there is almost entire loss of appetite and even a repugnance to food. This is an unfavorable feature of the disease. Disorder of digestion is sometimes so prominent as to appear to be the chief malady. The physician should be on his guard against considering the cough in such cases as merely dyspeptic or sympathetic. Antipathy to fat is by no means a constant feature of tuberculous cases; some patients take fatty articles of food freely without repugnance and with relish. And, on the other hand, not a few patients who are not tuberculous have an antipathy to fat.

Diarrhœa occurs, in the first stage, in a certain proportion of cases. If occasional only, it may proceed simply from incomplete digestion; but if frequently recurring or persisting, it points to the existence of a tuberculous affection within the intestinal canal, usually seated in the small intestine. Persisting or frequently recurring diarrhœa, accompanied by cough, if the latter be never so slight, should excite suspicion of pulmonary tuberculosis, and the existence of this affection being ascertained, a tuberculous affection of the intestinal canal, as a secondary affection, is to be inferred. Diarrhœa proceeding from tuberculous enteritis in an unfavorable symptom, diminishing the prospect of improvement. The seat of the affection is usually the Peyerian and solitary glands. It leads to ulcerations differing from those which are characteristic of typhoid fever in a tendency to extend in a transverse direction and to occupy only portions of the elliptical patches; also, in having hardened and raised margins. Tuberculous ulcerations are sometimes found in the large, as well as in the small, intestine, and they may be confined to the former. The ulcerations may lead to circumscribed peritonitis, and the peritoneal inflammation sometimes becomes general. Perforation of the intestine occasionally takes place, giving rise to general peritonitis, provided the peritoneal surfaces over the ulcerated space within which the perforation occurs have not become adherent from previous circumscribed inflammation.

Impaired nutrition, denoted by diminished weight or emaciation, is frequently one of the earliest symptoms. As a rule, reduction in weight continues so long as the disease is progressive; on the other hand, the disease may generally be considered as non-progressive if the patient be not losing weight, and, still more, if he be gaining in flesh. Defect in the processes of assimilation is shown also by anæmia, which, in most cases of pulmonary tuberculosis, is an early symptom, and frequently exists in a marked degree.

The muscular strength progressively diminishes if the disease be progressive, but here there is much variation in different cases. Patients are rarely compelled to keep the bed in the first stage, and they are generally able to be out of doors. Deficiency of breath, in some cases, precludes an amount of active exercise or labor for which muscular strength is sufficiently retained.

In females, suppression of the menses is a symptom significant of the progress of the disease; the menstrual discharge diminishes in quantity, and generally becomes suppressed. They are apt to attribute importance to the suppression as a cause of their other ailments. It is, however, an event incidental to the tuberculous disease, and does not claim special

measures of treatment. Facts do not show that suppression of the menses from other causes exerts an influence in the development of tuberculosis.

This disease does not tend directly to impair the intellectual faculties. The intellect frequently remains bright and active notwithstanding the progress of the disease. The feelings are usually cheerful and buoyant. Patients are hopeful respecting their condition; they depreciate their symptoms, and are reluctant to admit that the malady is serious. This state of mind sometimes amounts to an infatuation which renders it difficult to obtain from the patient a fair account of the symptoms, and it is necessary for the physician to rely chiefly on the statements of others and his own observations. To such an extent is the absence of anxiety characteristic of the disease, that an opposite frame of mind militates somewhat against the supposition of the existence of tuberculosis. Tuberculous patients are readily persuaded that they are improving, and hence they fall an easy prey to quacks. They sometimes dislike to be told the truth, and take offence at an intimation that they are consumptive.

Proceeding to notice the points in the clinical history which distinguish the second stage, it is to be borne in mind that it is not easy, nor is it practically important, to draw an exact line of demarcation between the two stages. Successive tuberculous irruptions are apt to take place, or the accumulation may be going on steadily, so that, while the local affection has advanced to the second stage in one part, usually near the apex, the first stage may be represented in other parts. The disease is to be considered as having advanced to the second stage when it has led to the formation of a cavity or of cavities of sufficient size to give rise to certain distinctive signs and symptoms. The symptoms of the first stage continue into the second, in most cases, being increased and modified by the existence of cavities.

The cough in the second stage usually becomes more prominent. It is less irritable, and more exclusively for expectoration. It is troublesome and difficult in proportion as the contents of the cavities are not easily evacuated, owing to their size, want of free communication with the bronchial tubes, etc. The expectoration consists of liquefied tubercle, matter furnished by the lining membrane of the cavities, and products of secretion from the bronchial mucous membrane. The quantity of expectoration is very variable, amounting, in some cases, to only a few ounces, and, in other cases, to a pint or more daily.

The appearances of the expectoration are various. It is oftenest mucopurulent with more or less predominance of the characters of pus. In proportion as it has the characters of pus, the sputa do not remain distinct, but run together to form a homogeneous mass. Sometimes a collection of the liquid expectorated presents a thick, opaque appearance not unlike that of pea-soup or gruel. The sputa are sometimes solid, remaining distinct, and, in falling upon the bottom of a vessel, assume a flat, round appearance like that of a coin, and hence are called *nummular sputa*. The sputa occasionally present yellow *striæ*, which consist apparently of pus. The edges of the sputa are sometimes ragged; another appearance is that of small particles, resembling boiled rice, contained in the matter expectorated. It is very rare for a semi-softened, cheesy, morbid product to be expectorated; but, in one case under my observation, several masses of this description were raised, evidently due to an unusually large ulcerated orifice being established between a tuberculous collection and a bronchial tube of considerable size. In this case, the signs of a cavity were developed directly after the expectoration of a large amount of matter which contained the partially softened masses. A sudden expectoration of mat-

ter, in considerable quantity, presenting a purulent or puruloid appearance, denotes the opening by ulceration of a so-called tuberculous abscess. Not infrequently this occurs repeatedly during the progress of the disease; but in many cases the ulcerated opening is at first small, and the liquefied matter escapes gradually into the bronchial tubes. The constituents, as shown by the microscope, are pus-globules, epithelium, fatty granules, blood-disks; occasionally the yellow elastic fibre, and sometimes vegetable sporules and spores.

The quantity of matter expectorated is, in general, in proportion to the number and size of cavities. It is usually more abundant in the morning than at any other period, owing to its having accumulated during sleep. Toward the close of life the act of expectoration becomes difficult on account of muscular feebleness, and the consequent accumulation of morbid products in the air-passages not infrequently hastens death. Occasionally the matter expectorated, and the breath of the patient, emit considerable fetor, due to sloughing of small masses of pulmonary structure within the cavities.

Hæmoptysis occurs less frequently in the second than in the first stage; and, occurring in the second stage, it may be due to the rupture of the bands of pulmonary tissue which so often traverse tuberculous cavities, these bands sometimes containing vessels of sufficient size to furnish an abundant hemorrhage. It is possible for the loss of blood in this way to be sufficient to destroy life, but instances are extremely rare. The hemorrhage, however, may contribute to a fatal result. I have known a large cavity to become filled with coagulated blood.

Hoarseness, or huskiness, and sometimes extinction of the voice, denote laryngitis, which may be developed in the first, as well as in the second, stage. This affection has been considered in the preceding chapter. It is to be borne in mind that its existence constitutes presumptive proof of pulmonary tuberculosis, the latter existing prior to the laryngitis.

Lancinating pains incident to circumscribed pleuritis recur in the second as well as the first stage, from time to time. Occasionally, both in the first and second stage, the pleuritis becomes general, and is attended with liquid effusion. So far as my observations go, they confirm the statement of Louis, that double pleuritis with effusion always denotes the pre-existence of tubercle. Acute pain, suddenly developed, with embarrassed breathing, acceleration of pulse, and prostration, point to perforation of the lung, and the signs of pneumo-hydrothorax are to be sought for.

The pulse, as a rule, is more accelerated in the second than in the first stage. Febrile exacerbations are oftener present and more marked, with burning of the soles and palms. The night perspirations are often copious, being a source of debility and great discomfort.

The appetite and digestion are more or less impaired, cases differing greatly as regards the symptoms connected with the ingestion of food. Diarrhœa is more frequently present and is a more prominent symptom in the second stage, being connected often with intestinal ulcerations. If profuse and persisting, it has been distinguished as *colliquative diarrhœa*. Colliquative diarrhœa occurs at an advanced period of the disease when tuberculosis of the intestines does not exist. It is then due to impairment of intestinal digestion, and to transudation from impoverishment of the blood. With the progress of the disease the body progressively diminishes in weight, and the patient is often reduced to an extreme degree of emaciation. The strength varies greatly in this stage. The patient may be confined to the bed for a greater or less period before death, but not infrequently strength is preserved sufficiently to be up much of the time,

and even to go out of doors, within a few days or even a few hours of death.

Bulbous enlargement of the ends of the fingers, with incurvation of the nails, forming what are commonly called *clubbed fingers*, is occasionally observed. This peculiar appearance is characteristic of tuberculous disease, but it is not a pathognomonic symptom. I have known it to be strikingly marked in connection with organic disease of the heart without tuberculosis, and also in chronic pneumonitis. The toes present a similar appearance, but in a less marked degree. This symptom occurs only in cases in which the disease has existed for a considerable period. Of 1776 cases analyzed by Pollock, the fingers were more or less clubbed in 654, being a fraction under 27 per cent.

The mental condition in the second stage is frequently not less characteristic than in the first. The expectation of improvement, prolonged life, or even recovery, amounts, in some cases, to an insane delusion. Patients are sometimes occupied in forming plans for the future, when it is obvious to any observer that they are on the verge of the grave. They may insist to the last that there is no danger. Over and over again, in the hospital pulmonary wards, I am asked by patients reduced almost to skeletons, and too feeble to sit up for a moment, if there be any danger, or if I do not think they will recover. But whenever patients affected with this disease are satisfied that there is little or no hope of recovery, they generally become quickly and completely resigned.

Œdema of the feet and ankles is a symptom of the second stage, denoting notable failure of the circulation. For a time this may occur only after sitting or standing, disappearing after the recumbent posture has been maintained for some hours; but, at length, it is permanent, and may increase and extend over the whole of the lower extremities, rendering them unwieldy or powerless. When the œdema becomes thus marked, extensive, and permanent, thrombosis, with, as a consequence, an obstruction of the crural veins, is to be suspected, an event which is liable to occur in this disease. Coagulation in the crural vein on one side will account for the œdema in some cases in which it is either limited to, or is much greater in, one of the lower limbs. If the œdema become diffused over the body, constituting anasarca, coexisting disease of the kidneys is to be inferred; but degenerative disease of the kidneys is a rare complication of pulmonary tuberculosis.

The clinical history, in cases of pulmonary tuberculosis, is affected, in no small degree, by complications and coexisting affections. The occurrence of tuberculous disease of the intestines, tuberculous laryngitis, pneumo-hydrothorax, and disease of the kidneys, has been already referred to. Chronic peritonitis is an occasional complication. The researches of Louis have shown that chronic peritonitis, not traumatic, is almost invariably dependent on tuberculosis in this situation, and hence that, from the existence of the peritoneal affection, pulmonary tuberculosis may be inferred. Acute peritonitis, from perforation, is sometimes incident to the ulcerations which proceed from the tuberculous affection within the intestinal canal. Meningitis occurs as a rare concomitant in the adult, but not infrequently in early life. This coexisting affection accounts for the development of delirium and coma in certain cases. Perineal abscess, leading to fistula, is another complication occurring in a certain proportion of cases, proceeding probably from tubercle in this situation. Clinical observation shows that, as a rule, when this complication occurs, the amount of tubercle in the lungs is small or moderate, and the progress of the pulmonary affection is slow. An accumulation of fat within the liver

cells is a morbid condition observed in a small proportion of cases, occurring oftener in females than in males.

The duration of this disease is extremely variable. In the vast majority of cases it is essentially a chronic affection, but sometimes it runs a rapid course, passing through its changes and destroying life in a few weeks. The disease in such cases has been known as "galloping consumption." The disease, in these cases, is quite different from that known as *acute phthisis*, which will be noticed briefly under a distinct heading.[1] Distributing fatal cases into groups according to the duration of the disease, exclusive of the rapid cases just referred to, one group will consist of cases in which the disease continues from three to six months; in another group, death takes place between six months and a year; in a third group the career extends from one to two years; and in another group the fatal termination is held in abeyance for many years; I have met with a number of persons who have been tuberculous for more than twenty years, and a patient was for a long time under my observation in whom there is reason to believe the disease existed for forty years.

Limiting attention to the cases in which, sooner or later, the disease proves fatal, its march is extremely irregular. It is not uncommon for little or no progress to be apparent for several successive weeks, months, or even years, and then the disease to advance with more or less rapidity. Distinct tuberculous irruptions occurring at successive periods are frequently points of departure for the onward march of the disease; but cases differ much as regards the local destruction, changes incident to the collections of tubercle, and the rapidity with which softening, ulceration, and the formation of cavities take place. Further remarks on the march of the disease will be offered under the head of prognosis.

Pathological Character.—The pathological character of this affection has already been considered in the first part of this work. In a practical point of view, the fact to be especially borne in mind is that pulmonary tuberculosis is not, primarily and essentially, an affection of the lungs. The tuberculous products proceed from a prior morbid condition of the system; in other words, the pulmonary disease is the local expression of a special constitutional affection called the tuberculous cachexia or dyscrasia. It is a rational inference that a vice of assimilation is involved in the existence of the tuberculous cachexia, but the nature of the latter and the mode of its production are problems remaining to be solved by future researches. Grounds for the foregoing statement as regards the constitutional origin of pulmonary tuberculosis will appear in proceeding to consider the causation.

Causation.—The causes of pulmonary tuberculosis may be divided into those which act, first, locally, upon the lungs; and, second, generally, or upon the system, in producing the constitutional condition or cachexia which constitutes the disease. With respect to local causes, it may be doubted whether they are ever sufficient in themselves to produce the disease. It is probable that they only act as exciting causes. The tuberculous affection is sometimes either preceded by, or occurs in connection with, some other pulmonary affection, viz., bronchitis, pleuritis, or pneumonitis. If this association be more than a coincidence, the latter affections only serve to determine the local manifestation, the cachexia already existing;

[1] By some writers the term "galloping consumption" is applied to the latter form of disease.

that is, they act the part of the match when everything is ready for the explosion. These affections occur so frequently without being either accompanied or followed by tuberculosis, that it is certain they have no intrinsic tendency to that result; and, on the other hand, in the great majority of cases, pulmonary tuberculosis is developed irrespective of these affections. It has been supposed that the inhalation of irritating substances, such as stone-dust, fine particles of metal, etc., necessarily incidental to certain occupations, is sufficient to give rise to tuberculous disease. Even this may be doubted. When the disease attacks needle-grinders, stone-cutters, etc., causes are probably involved other than those acting locally, the latter playing only a subordinate part in the etiology. The inhalation of irritating substances gives rise not infrequently to chronic interstitial pneumonitis accompanied by signs and symptoms which render it not easy to differentiate the affection from tuberculosis.

The statements in the foregoing paragraph are not in accordance with views held by some late writers, namely, Niemeyer and others. According to these views, the development of pulmonary tuberculosis, that is, of the yellow tuberculous product, is often dependent on bronchitis. Hence, the name adopted by Niemeyer, *chronic catarrhal pneumonia.* Niemeyer and others, indeed, go so far as to attribute the development of this tuberculous affection chiefly, or entirely, to a bronchitis or bronchial catarrh, attributing little or no importance to a diathetic or constitutional agency. A question of this kind is settled not by a theory based on histological observations, but by clinical facts. Now the early clinical history, in cases of tuberculous disease, shows, as already stated, that a bronchitis, or bronchial catarrh, rarely precedes the symptoms and signs which denote tuberculosis. I make this positive assertion with the utmost confidence in its correctness, inasmuch as it is based on the study of a large number of cases with reference to the earliest symptoms and signs. Moreover, it accords with the clinical researches of Louis, which, so far as they go, are as reliable and as valuable to-day as when they were made, now nearly half a century ago. Aside from clinical facts, it is certainly irrational to suppose that a bronchitis, which is a bilateral disease, should give rise to an affection almost uniformly limited, at first, to the apex of one lung. The doctrine that the development of pulmonary tuberculosis is dependent on bronchitis, or other local causes, rather than on an unknown constitutional agency, called a cachexia, is the more to be protested against, since, upon this doctrine are based prophylatic and therapeutical measures which are opposed by clinical experience.

Niemeyer attributed the production of phthisis, in some cases, to bronchorrhagia, the presence of blood remaining in the bronchial tubes being supposed to prove a local cause. As already stated, clinical observation, so far from affording ground for this opinion, goes to show that hæmoptysis is oftener a salutary event than otherwise, if tuberculous disease already exist; and there is reason to think that it is sometimes a substitute for, and, therefore, preventive of, tuberculosis. But in some rare, exceptional cases an attack of hæmoptysis appears to be the point of departure for either the development or the active progress of tuberculous disease.

To the conformation of the thorax was formerly attributed considerable causative agency. This doubtless arose in part from observing that tuberculous patients often present contraction of the chest, occurring as an effect of the disease. Persons with great deformity of the chest are not specially prone to tuberculosis. So, also, the idea that the exercise of the voice may be a predisposing or exciting cause, has become obsolete; and

observation shows that, if any influence be derived from this source, it is conservative rather than causative.

The opinion appears to be entertained by some writers, that chronic pharyngitis, which is an exceedingly common affection in this part of the world, has a tendency to eventuate in pulmonary tuberculosis. I am satisfied that this opinion is erroneous. After a large opportunity of observing cases of chronic pharyngitis, I have come to the conclusion that it generally denotes a condition of the system unfavorable to tuberculous disease. The sebaceous collections which are liable to accumulate in the glands of the tonsils, and to be ejected by coughing in the form of round, hard pellets, are sometimes mistaken for tubercles. These may be distinguished from obsolete tubercles or pulmonary calculi by their being unctuous to the touch, and emitting, when crushed, a fetid odor.

The efficient causes of pulmonary tuberculosis must be sought for among those which affect the system. Were the essential nature of the disease understood, we might hope to reach, synthetically, the knowledge of its causation. A rational pathology and etiology must of necessity go hand in hand; but our present knowledge of both is confined within narrow limits. The actual knowledge which we possess is derived from clinical observation and statistics, and there is much room for further information to be derived from these sources. I shall state certain conclusions which appear to be well grounded, referring the reader, for a fuller exposition of the facts on which they are based, to works treating at greater length of this most important branch of the subject.

Facts show the tuberculous diathesis in a certain proportion of cases to be congenital and inherited. Why a peculiarity of constitution rendering a person specially liable, at a certain age, to the development of this disease should be transmitted from parent to child, cannot be explained more than the fact that peculiar traits of physiognomy or mental character are inherited. The conclusion rests on observation. It is a matter of common remark that the offspring of consumptive parents are apt to become tuberculous. But it is to be borne in mind that, owing to the frequency of the disease, a tolerably large proportion of tuberculous parents must have a consumptive parentage from mere coincidence; and it may be true that, sufficient consideration not having been accorded to this fact, hereditary influence has been overrated. Walshe's statistical researches appear to give support to this supposition. Interrogating a considerable number of hospital patients affected with the disease, viz., 162, he found that of this number in 26 per cent. either the father or mother, or both parents, were tuberculous.[1] He argues that this proportion is not much above that which would be expected from the prevalence of the disease irrespective of any hereditary influence. These statistics, however, are open to the criticism that the statements of hospital patients are not very reliable, and that, in a certain proportion of cases, the parents might subsequently become tuberculous. Moreover, the number of patients interrogated, although considerable, was not very large. The plan of investigation might be pursued farther with perhaps a different result; and it would be more satisfactory to analyze cases in private practice with respect to this point.

A congenital and hereditary influence is most strikingly shown by facts relating to certain families. In another work I have cited the following instance, occurring under my own observation:[2] All the children of a

[1] British and Foreign Med.-Chir. Rev., Jan. 1849.

[2] Physical Exploration of the Chest, and the Diagnosis of Diseases affecting the Respiratory Organs. 1866.

family, seven in number, were victims of this disease in five years—the ages being between 18 and 23. The mother died of the disease shortly before the death of the first of the seven children who died. The father was a man of robust health. Another instance within my knowledge is as follows: A tuberculous patient was under my care in January, 1862, and subsequently died. This patient had lost eight brothers or sisters from the disease, and both parents. Two sisters, then living, were all that remained of the family. Another striking illustration is afforded by the following facts: Of a family comprising eight children, one died in childhood with convulsions, three daughters and one son have died with phthisis, another daughter and a son are now tuberculous, and the only remaining child, the eldest daughter, presents the history and signs of arrested tuberculosis. Both parents died tuberculous. The following statement, communicated to me by Dr. Henry E. Paine, of Dixon, Illinois, illustrates a congenital tendency without the evidence of inheritance: Mr. S. is 57 years of age, and in good health. His wife is 52, and well. No progenitors have been known to die with tuberculosis. All the children, five in number, died with this disease between 1853 and 1861—their ages respectively being, at the time of death, 23, 25, 24, 22, and 23. The following facts are interesting as showing a remarkable limitation of the disease to one branch of a family: Two brothers married sisters. In neither family was there evidence of hereditary predisposition to tuberculous disease. One of the brothers and his wife died of the disease. Of two sons and two daughters, both the latter and one of the sons have died with the disease; and the remaining son is probably tuberculous. The other brother and his wife are living in good health, and of several children, none have been affected with tuberculous disease.

Facts, such as have just been cited, certainly show that the tuberculous diathesis is sometimes inherent in the constitution and inherited. To what extent a congenital influence is involved in cases in which circumstances do not render it evident, must be left for conjecture. It is not irrational to suspect its existence in a large proportion of the cases in which proof is impossible.

The predisposition has relation to age. The disease is most liable to be developed between 20 and 30. The other decennial periods of life are arranged in the following series, according to the rate of predisposition: 30 and 40, 10 and 20, 40 and 50, 50 and 60, 0 and 10, 60 and 70, 70 and 80, 80 and 90, 90 and 100. No age is exempt from a liability to the disease, and it may affect the fœtus *in utero*.

Climate appears to exert an influence either for or against the development of the disease. It may be stated that the prevalence of the disease is less in climates either uniformly warm and dry, or uniformly cold and dry, than in those which are moist and subject to frequent alternations of cold and warmth. A high altitude appears to afford protection against the disease. Jaccoud states that observations for fifteen consecutive years warrant him in asserting that in Alpine situations elevated 4000 feet, tuberculosis is almost unknown; and especially is this true of villages at an elevation of 5500 feet, where, in the language of the country, there are "nine months of winter and three months of cold weather." According to Dr. Hjaltelin, who resides in Iceland, the inhabitants of that country enjoy exemption from phthisis. The disease prevails to a much greater extent in cities than in the country, showing, doubtless, the operation of auxiliary causes in the former. It prevails more on the seaboard than in inland situations. The elaborate researches of Prof. Bowditch go to show that, in the State of Massachusetts, cases occur more frequently in localities in

which the atmosphere is rendered humid by streams or marshes. Dr. Buchanan's observations show that, in England, cases are comparatively rare in dry, elevated situations. There is no foundation for the opinion that the terrestrial emanations known as malarial afford any protection against the disease. Newly-settled places are frequently exempt, for some time, from its prevalence to much extent; but the explanation of this fact is, the pioneers who compose the early population in these places are persons, generally, of sturdy, vigorous health, and the habits of life, in such a population, are protective against this disease. As regards season, the disease is oftener developed during the spring months and the hot months of summer than at other portions of the year.

The disease prevails much more among those whose pursuits are sedentary than among those whose occupations involve out-door life. Want of exercise, defective ventilation, deficiency of light, and the depressing emotions undoubtedly contribute to the production of the tuberculous cachexia. With reference to the influence of ventilation, the following researches of Dr. Guy, of London, are interesting: Taking hæmoptysis as a criterion of either tuberculosis or the tuberculous cachexia, Dr. G. interrogated 104 compositors who worked in apartments having less than 500 cubic feet for each person. Of this number thus situated, 12.50 per cent. had had hæmoptysis. He then interrogated 115 compositors who worked in apartments having from 500 to 600 cubic feet, and of this number 4.35 had had hæmoptysis. Of 101 compositors working in apartments with more than 600 feet only 1.98 had had hæmoptysis. The influence of the several causes just mentioned is seen in the greater liability of domesticated animals to tuberculous disease than of the same animals in a wild state. "The stabled cow, the penned sheep, the tame rabbit, the monkey, the caged lion, tiger, or elephant, are almost invariably cut off by tuberculous affection."[1]

The infrequency with which the disease is found in the post-mortem examinations of those who have died from intemperance, has led to the supposition that the use of alcohol antagonizes the tuberculous cachexia. Assuming that there is ground for this supposition, it would be irrational to reject it because it may be made to sanction the unnecessary use of alcohol; but the moral, as well as physical considerations which this application involves are, of course, to have due weight in affecting the conduct of practitioners. The following statistical facts relating to the prophylactic influence of alcoholism have been communicated by Leudet:— Of 121 persons addicted to the use of alcohol, twenty were tuberculous, and these twenty were the only intemperate persons among 600 tuberculous patients.[2] There is reason to believe that habits of diet unduly restricted as regards variety and quantity, either from choice or necessity, may contribute to the development of the disease.

Pregnancy has been supposed to antagonize the tuberculous cachexia, and marriage has sometimes been advised as a prophylactic and even curative measure. Facts, however, do not afford support to this supposition. The researches of Grisolle and Dubreuilh show that, so far from this being true, the development of the disease not infrequently takes place during pregnancy, and when tuberculous patients become pregnant, the progress of the disease is hastened rather than retarded. Of 155 cases in patients who had recently been confined, analyzed by Pollock, in 48 the disease was developed during pregnancy, and in 51 it began at confinement.[3] An

[1] Aitken, Science and Practice of Medicine. [2] Hérard and Cornil, *op. cit.*
[3] The Elements of Prognosis in Consumption, by James Edward Pollock, M.D. London, 1865.

analysis, by the same author, of 94 cases in which the disease was developed after confinement, showed that it began during lactation in 54. Clinical facts are opposed to the notion, that the progress of the disease is retarded by lactation.

Certain diseases exert an influence, on the one hand, to promote, and, on the other hand, to prevent the development of tuberculosis. It rarely occurs in persons affected with pulmonary emphysema. Persons affected with cardiac lesions which interfere with hæmatosis, rarely become tuberculous. On the other hand, measles and typhoid fever leave the system in a condition favorable for the development of the tuberculous cachexia. Are they who suffer in early life from a scrofulous affection of the lymphatic glands of the neck especially prone to pulmonary tuberculosis in after-life? I have been led to think that this question may be answered in the negative. I have collected a number of cases in which young and middle-aged persons presenting the characteristic cicatrices on the neck were free from tuberculous disease of the lungs; and, on the other hand, it is extremely rare to find these cicatrices in persons who are affected with pulmonary tuberculosis. Assuming the tuberculous and the scrofulous cachexia to be the same, it would seem that it is, as it were, exhausted by the deposit in the glands of the neck, and that afterward it is not likely to recur. Contrary to what might be expected *à priori*, anæmic persons rarely become tuberculous. Pollock states that of 125 carefully noted cases of anæmia, with murmurs, in none was there any sign of tubercle. The association of anæmia with pulmonary tuberculosis, except as a complication or an effect, is certainly rare. It is rare for tuberculosis to follow an attack of lobar pneumonitis.

In conclusion, of the various agencies which are involved, more or less, in the causation of pulmonary tuberculosis, it is difficult to assign to each its proper relative importance. It is probable that this is pre-eminently a diathetic disease; but it is impossible to determine whether the diathesis be always innate, or whether, in a certain proportion of cases, it be acquired. Do the causes which contribute to the development of the disease produce the diathesis, or do they act solely by producing the cachexia, the diathesis already existing? Our present knowledge does not enable us to answer this question. Yet our limited knowledge of the causation is of immense value in its practical application to prophylaxis and treatment.

The production of tuberculous disease in certain inferior animals by inoculating them with matter obtained from the tuberculous products in man has been already referred to (*vide* Part I., p. 40). The discovery of this interesting and important fact naturally leads to the inquiry whether pulmonary tuberculosis may not sometimes be caused in man by the inhalation of a virus contained in the breath or exhalations from the body of tuberculous patients. The doctrine of the contagiousness of the disease has now, as hitherto, its advocates, but the general belief of the profession is in its non-communicability. The advocates for the doctrine have relied for its support especially on the number of instances in which husbands and wives have been affected in succession. If the communicability of the disease by inoculation establish the existence of a specific virus, this fact would lend considerable support to the doctrine of contagiousness.

CHAPTER XI.

PULMONARY TUBERCULOSIS—(Concluded.)

Diagnosis—Prognosis—Treatment. Acute Pulmonary Tuberculosis.

DIAGNOSIS.—A positive, and, especially, an early diagnosis, in cases of pulmonary tuberculosis, must rest mainly on physical signs, in connection with the history and symptoms. A full consideration of the physical diagnosis does not fall within the scope of this work. For this, the reader is referred to treatises devoted to physical exploration, or to diseases of the chest.[1] I shall content myself with giving an enumeration of the important signs involved in the discrimination of the disease, and, afterward, recapitulate the diagnostic symptoms embraced in the clinical history.

The physical conditions, when the amount of tubercle is abundant or when the disease is advanced to the second stage, are represented by well-marked signs, rendering the diagnosis sufficiently easy and positive. The diminished volume of lung at the apex, which frequently occurs, causes a depression at the summit of the chest on the side most affected, and, owing to pleuritic adhesions, the expansion, at the summit, is less than on the opposite side. The scapula, on the side most affected, is often restrained in its movement upward in inspiration, contrasting, in this respect, with the opposite scapula. These signs, obtained by inspection, are available in a certain proportion of cases. Percussion elicits relative dulness, and sometimes even flatness, over the tuberculous collections. Exceptionally, over the solidified portion of lung, the resonance is tympanitic. A tympanitic resonance over a circumscribed space, and the varieties of this resonance called cracked metal and amphoric, point to the existence and situation of cavities. The respiratory sound, obtained by auscultation, is either bronchial, broncho-vesicular, or cavernous, and, not infrequently, these different signs are found in different situations, in the same case. The first represents considerable or complete solidification, the second moderate or slight solidification, and the third a cavity or cavities. The cavernous respiration, in some cases, has an amphoric quality. The correlative vocal signs are likely to be present, namely, either bronchophony with the loud and whispered voice, or exaggerated vocal resonance, and, in rare cases, pectoriloquy. More or less of these auscultatory signs are available in the great majority of cases. And these, taken in connection with the cough and expectoration, the emaciation, and other symptoms belonging to the history of the disease, render the diagnosis almost always an easy problem.

It is only in cases in which the quantity of tubercle is moderate or small, the symptoms being, at the same time, less marked, that the diagnosis is difficult; and the difficulty, in such cases, is rarely great, provided

[1] The author has considered at length the physical diagnosis of this as well as other pulmonary affections, in his work entitled Physical Exploration of the Chest and the Diagnosis of Diseases affecting the Respiratory Organs. Second edition, 1866.

the physician have a good practical knowledge of physical exploration. Inspection may, in these cases, furnish the same signs, but less marked than in cases of abundant tubercle. As a rule, slight or moderate, but distinct, dulness on percussion may be ascertained. The exception to this rule is when more or less of the pulmonary lobules become emphysematous, and then the resonance is altered, although not diminished—it is vesiculo-tympanitic. A comparison of the respiratory murmur on the two sides at the summit, will be likely to show abnormal changes, viz., the characters of the broncho-vesicular (rude) respiration. So, also, on a comparison as regards vocal signs, the vocal resonance and the bronchial whisper may be found to be exaggerated. The same is true of vocal fremitus. A careful exploration with reference to the foregoing signs, will furnish direct evidence of the disease.

In addition to these signs, there are several, occasionally present, which are inferentially evidence of tuberculosis. These may be distinguished from those already enumerated, as the accessory signs of the disease. Fine mucous or the subcrepitant rales, heard within a circumscribed space at the summit of the chest on one side, are highly significant of tubercle. They proceed from circumscribed bronchitis excited by the presence of a tuberculous product. A crepitant rale, in like manner limited to a small space at the summit on one side, has the same significance, being due to circumscribed pneumonitis excited by the tuberculous product. Crumpling and crackling sounds, also, are significant, provided they be limited to the summit on one side. A pleural friction sound limited to the summit on one side denotes a circumscribed pleuritis which is probably secondary to a tuberculous affection. Other accessory signs are, an abnormal transmission of the heart-sounds, and an interrupted or jerking respiration. The diagnostic significance of all these signs, it will be observed, depends on their situation at the summit of the chest on one side. Separately they are not sufficient for the diagnosis, but, coexisting with the direct signs, viz., dulness on percussion, broncho-vesicular respiration, exaggerated vocal resonance, and increased bronchial whisper, they serve to confirm these signs and render the diagnostic evidence positive.

The diagnostic points pertaining to symptoms, to which attention is to be directed in determining whether the disease be or be not present, when the signs are not so well marked as to render the diagnosis easy, are as follows: (*a.*) Cough and expectoration, not succeeding an attack of acute bronchitis, and not connected with chronic pharyngitis; the cough at first dry, and, afterward, an expectoration, at first small and transparent, and becoming gradually more abundant and opaque. (*b.*) Stitch-pains at the summit, not connected with intercostal neuralgia. (*c.*) Chills not referable to malaria. (*d.*) Hæmoptysis. This is always a symptom of great significance, but the fact is to be borne in mind that it occurs, in a certain proportion of cases, without being associated with tubercle. (*e.*) Accelerated breathing. (*f.*) Loss of weight. (*g.*) Pallor or anæmia, not otherwise explicable. (*h.*) Hoarseness or huskiness of voice, proceeding from chronic laryngitis. (*i.*) Chronic peritonitis, not traumatic. (*j.*) Suppression of the menses. (*k.*) Buoyancy of mind, instead of despondency.

Facts which render the existence of a hereditary predisposition probable, are to be taken into account in the diagnosis. The age of the patient is another point. As the discrimination frequently lies between tuberculosis and chronic bronchitis, it is to be considered that, except in aged persons and those affected with disease of the heart, chronic bronchitis is comparatively so rare that the chances are in favor of the existence of tu-

berculosis. The chances are still greater, if, in addition, are excluded the cases in which chronic bronchitis is associated with asthma and emphysema, affections which rarely coexist with tuberculosis.

In certain cases of pulmonary tuberculosis the solidification represented by physical signs at the time of an examination of the chest depends, to a greater or less extent, on an intercurrent, transient, circumscribed pneumonitis. This can only be ascertained by repeated examinations of the chest after certain intervals of time. The solidification, so far as due to superadded simple or ordinary pneumonic inflammation, will be found to disappear, leaving that which is caused exclusively by the tuberculous affection. If the solidification, as ascertained by physical signs, be unreservedly attributed in all cases to the tuberculous products, the practitioner will sometimes be led to over-estimate the amount of the latter. It is important, therefore, to bear in mind the liability to a temporary increase of solidification of lung, in cases of tuberculosis, from an intercurrent pneumonitis which may not reveal itself by any distinctive symptoms.

Prognosis.—The prognosis, in cases of pulmonary tuberculosis, is extremely unfavorable, in view of the fact, that, in many, if not most, parts of the world, the mortality from this disease exceeds that from any other, exclusive of fevers and affections which prevail epidemically or endemically. Yet the mortality from the disease has undoubtedly diminished within the past ten or fifteen years. This must be obvious to medical observers whose professional experience extends backward a quarter of a century or more. The fact is also shown by the statistics published by the registrar-general of Great Britain, and by the mortuary reports of the large cities in this country. The explanation of the fact is probably to be found in improved views as regards the management of the disease. The diminution which has already taken place in the death-rate from this disease, affords ground for the hope that its formidable character may be still further mitigated.

The different modes in which the disease may pursue a favorable course have been already stated. The entire deposit may be absorbed, or the animal portions may be absorbed, the mineral constituents remaining in the form of obsolete tubercles or calculi, and these may remain quiescent, or they may find their way into the bronchial tubes and be expectorated. Cavities may completely cicatrize. In these modes complete recovery may take place. This, of course, is the most satisfactory termination. And next to this is the persistence of cavities without any fresh products, the cavities giving but little inconvenience for an indefinite period, and even through a long life. According to these different modes in which the course of the disease is favorable, cases may be divided into those in which an arrest takes place without recovery, and those in which the arrest is followed by recovery. Whether recovery follows, or not, the arrest will depend on the amount of tubercle, and other circumstances. Not infrequently an arrest takes place, with or without recovery, and, after the lapse of several months or years, a fresh irruption of tubercle occurs. The latter, then, is not properly a continuance of the disease, but a relapse. These distinctions seem to be pathologically just, and they are practically important.

Pulmonary tuberculosis may end in recovery from an intrinsic tendency, that is, without any therapeutic or hygienic measures having been employed. Of sixty-two recorded cases in which an arrest of disease took place, in seven this arrest was irrespective of any extrinsic influences, and

in four of these seven cases the recovery was complete.[1] To what an extent an intrinsic tendency to arrest is involved in cases is which measures of management are employed, it is difficult to say, but it is fair to conclude that this tendency enters more or less into many, if not most, of the cases which pursue a favorable course. Assuming this conclusion to be correct, it becomes an important question, what circumstances denote an intrinsic tendency to arrest, or, in other words, what circumstances encourage a favorable prognosis in this disease? The answer to these questions should be based on a comparison of the results of the analyses of collections of cases ending, on the one hand favorably, and, on the other hand, unfavorably. Such a comparison, as an object of clinical research, claims more attention than it has, as yet, received. I shall give certain conclusions, based chiefly on the study of a considerable number of cases pursuing a favorable course under my own observation.

A small amount of tubercle, and a stationary condition as regards the amount, are favorable circumstances. An arrest may take place although the amount of tubercle be large, but it is obvious that, inasmuch as the local damage is proportionate to the amount, the prospect of recovery is better the less the quantity of tubercle. Another favorable circumstance is the quiescence of the disease, as denoted by the local and general symptoms. Tolerance of the affection is shown by the cough and expectoration being slight, whereas, the prominence of these symptoms indicates a proportionate local disturbance. The symptoms denoting general disturbance are, acceleration of pulse, chills, sweating, and debility. The prospect is favorable in proportion as these symptoms are wanting or without prominence. It may be here stated that the local and general disturbance are by no means uniformly in proportion to the amount of the tuberculous affection; they are sometimes marked when the amount of tubercle, as determined by physical signs, is small, and, on the other hand, they are slight in cases in which the amount of tubercle is large. It is evident that the constitutional symptoms are not exclusively symptomatic of the local affection. The import of hæmoptysis has been already considered. The observations of Ware and Walshe have shown that, as a rule, the prospect is more favorable in the cases characterized by the repeated occurrence of hæmoptysis, and my own observations have led me to the same conclusion.

The condition of the appetite and digestion affects the prognosis. The probability of arrest is greater in proportion as the appetite is good and the digestive organs free from disorder. It is a favorable circumstance if fatty articles of food can be taken without repugnance or disturbance of digestion, and if alcoholic stimulants be well borne. Diarrhœa is always an unfavorable symptom, whether functional or proceeding from tuberculous disease of the intestine. The condition as regards weight furnishes, on the one hand, one of the most favorable of prognostics, and, on the other hand, the most striking evidence of the unfavorable progress of the disease. The prospect is favorable if the loss of weight have been small and if it be not progressive, and, *per contra*, the prospect is unfavorable in proportion to the degree of emaciation and the rapidity with which it is going on.

The occurrence of perineal fistula is favorable, and so I have been led to regard laryngitis, excepting the cases in which the epiglottis and top of the larynx are involved, so as to interfere with deglutition. Facts

[1] Clinical Report on the Management of Pulmonary Tuberculosis. By Austin Flint, M.D. Trans. N. Y. Acad. of Med., 1863.

which go to show a strong hereditary or congenital tendency to the disease are unfavorable. Finally, energy of character and a determined will are highly favorable, by securing a faithful and persevering employment of the hygienic measures upon which the successful management of the disease mainly depends.

The disease proves fatal generally by asthenia. It is rare for tubercle to be so abundant, or the destruction of lung to be so great, as to destroy life by apnœa. The patient is gradually worn out by the protracted disturbance occasioned by the disease, conjoined with progressive emaciation and exhaustion. The development of pneumo-hydrothorax from perforation is apt to prove fatal in a short time, and sometimes by apnœa. Acute peritonitis from perforation has been known to occur, and this affection is likely to prove rapidly fatal. Meningitis is another complication which hastens the fatal termination.

Hæmoptysis is very rarely an immediate cause of death. A case has, however, fallen under my observation in which profuse hemorrhage occurred day after day in connection with a small amount of tubercle, and the patient died apparently from the loss of blood. A profuse and rapid flow of blood may occasion death by suffocation, the blood filling the bronchial tubes. As a rule, hæmoptysis, so far from denoting immediate danger, is a favorable event as regards the prognosis.

Treatment.—The point of departure for the consideration of the management of this affection is the pathological fact that the local affection is the expression of a general or constitutional morbid condition, the latter being the essential disease. The great object of treatment, therefore, is the removal of this constitutional morbid condition or the tuberculous cachexia. Measures addressed to the pulmonary affection are of secondary importance. The chief end to be kept in view is the prevention of the further production of tubercle, or, in other words, an arrest of the disease. It is immensely desirable for the arrest to take place as quickly as possible, while the amount of tubercle is limited and the pulmonary damage proportionably small; and with a view to a speedy arrest, the importance of an early diagnosis can hardly be overrated.

Is the tuberculous cachexia removable by any known special remedy or remedies? This question is to be answered distinctly in the negative. Various remedies at different times have been supposed to exert a specific curative influence over this disease. Thus, going back only a quarter of a century, during this period wood-naphtha, cod-liver oil, phosphate of lime, the hypophosphites, and the chlorate of potassa have successively been advocated as effecting a cure in cases of pulmonary tuberculosis. Few, if any, at the present moment consider either of these remedies, or any other remedy, as specifically curative. This, however, is by no means saying that these remedies are not useful in cases of pulmonary tuberculosis. Important indications are to be fulfilled by remedies, but it should be clearly understood that far more reliance is to be placed on hygienic than on medicinal measures of treatment.

Certain therapeutic measures which have heretofore been employed, to a greater or less extent, under the guidance of false pathological views, undoubtedly do harm rather than good. In this category belong bloodletting, either general or local, blisters and other severe modes of counter-irritation, mercurialization, antimonial and other nauseating preparations, emetics, and cathartics. These are contra-indicated. In general terms, everything is to be avoided which tends to impair the appetite, disorder digestion, and lower the vital powers.

The measures indicated are those which tend to strengthen and invigorate. These terms, although lacking scientific precision, have a practical significance which is sufficiently intelligible. Directing attention to the measures which fall under the head of hygiene, these relate to diet, exercise in the open air, clothing, mental encouragement, and change of climate.

The diet of tuberculous patients should be generous as regards quantity, quality, and variety. The articles should be highly nutritious and adapted to the digestive powers. All the varieties of wholesome food which the patient is able to take with relish should be allowed, and the appetite should be encouraged as much as possible. With respect to the kinds of food to be particularly recommended, there are no general rules which are applicable to all patients. Meats, milk, farinaceous articles, and the different vegetables are to be combined in relative proportions according to the choice, habits, and experience in individual cases. It is desirable that cream, butter, and other fatty articles should enter into the diet as largely as possible without inducing disgust and disorder of digestion. The same remark applies to sugar. The intervals between taking food should be such as will secure the largest amount of nutriment which can be taken and digested during the twenty-four hours. In short, it is far from desirable to arrange any fixed system embracing details of dietetics to which all patients are expected to conform. The object is to nourish the body to the fullest possible extent, and this requires, in every case, the co-operation of the physician and patient. Deficiency of appetite, especially for nutritious articles of diet, and weak and disorganized digestion, are apt to prove serious difficulties in the way of the successful management of the disease. Much may be done by persevering efforts on the part of the patient, and he should, therefore, be made to understand the object which it is desired to effect.

A diet consisting largely, or even chiefly, of fresh milk has undoubtedly proved sometimes successful, and a trial of it may be advised when the appetite is deficient, or when other articles of food occasion dyspeptic disorders. Goats' milk and asses' milk are rarely used in this country. They have heretofore been, and are still, to some extent, in European countries, considered as preferable to the milk of the cow. In order to carry out effectually the "milk cure," as it is sometimes called, milk should not only constitute the chief article of diet, but it should be taken largely.

Exercise in the open air, or, as I would prefer to say, out-of-door life, is, of all measures, the most important. In a paper already alluded to, on the management of pulmonary tuberculosis,[1] I have analyzed the recorded histories of sixty-two cases in which an arrest took place, with a view to the points in the treatment which were common to all or a greater or less number. In twenty of these cases the arrest took place under hygienic measures without medicinal treatment. In these cases the most important point of agreement related to change of habits as regards exercise and out-of-door life. In respect to this point, there was also an agreement in the cases in which medicinal measures were employed. The following extract from the paper contains a summary of the facts, with the general conclusions: "The most striking and valuable of the results of the analytical study of these cases is their almost uniform agreement as regards change of habits with respect to exercise and out-of-door life at the time of the arrest. Excluding the seven cases in which the arrest was attributable solely to an intrinsic tendency, and two cases in which the facts with respect to this point were not noted, of the remaining fifty-

[1] Trans. N. Y. Acad. of Med., 1863.

three cases, in all, save three, the histories show a greater or less change of habits to have been made; and in many cases the change consisted in relinquishing sedentary callings for other pursuits, in order to carry out more effectually the desired reformation. I am well satisfied that here is the foundation for the successful management of pulmonary tuberculosis. I would rank exercise and out-of-door life far above any known remedies for the cure of the disease. There are grounds for believing that the advantage of a change of climate mainly consists in its being subsidiary to a change of habits as regards exercise and out-of-door life. So deeply impressed am I with the correctness of this view of the regimenal management of the disease, that I cannot express myself too emphatically in trying to enforce its practical importance."

Tuberculous patients should sleep in well ventilated rooms. In conformity with popular notions, they are apt to fear the cool or cold air of night. A fire may be kept in sleeping-rooms in the winter season, but the windows should be kept open. Dr. James Blake, of San Francisco, California, has reported several cases in which most favorable results followed living in the open air during the summer months, at an elevation of from three to five thousand feet above the sea, in the coast range of the mountains of California where the temperature is very equable, and no rain falls for five or six months. The patients did not even sleep in tents, but were in the open air during night and day.

Exercise in the open air should be accompanied by either mental recreation or occupations which interest the mind. It should, as far as possible, be incidental to pursuits which engage the attention. Adopted simply as a hygienic measure, it will rarely be persisted in. It is often essential, therefore, for patients to make a radical change in business, or, if they be able to devote their time to the restoration of health, hunting, sporting, travelling, etc., are to be resorted to as means of securing the union of out-of-door life with an agreeable exercise of the mental faculties. Over-exercise of the muscles is to be avoided. Patients sometimes, supposing that the benefit from muscular exercise is proportionate to its amount, carry it to the extent of producing a degree of fatigue and exhaustion which is injurious. It is not from the amount of physical exertion, but of out-of-door life with such exercise as is well borne, that benefit is to be expected.

The body should be protected against atmospherical changes, the temperature and functions of the skin being maintained by warm clothing. The garments worn next the surface should be made of a material which is a good non-conductor of heat, viz., either wool or silk. But a superfluity of clothing is to be avoided. The object is to provide adequate protection, without an undue accumulation of heat and perspiration. In a cold or temperate latitude, during the winter season, a waistcoat of buckskin or chamois leather, worn, during the daytime, over a light woollen or silk shirt, is to be recommended to patients of either sex, as securing the proper protection without the inconvenience of being bundled with an overplus of garments. The feet should be well guarded against cold and wet. Properly clothed, the patient, if he be strong enough to go out of doors, should rarely be kept within doors by the state of the weather, but should resolutely keep up habits of out-of-door life, despite the ordinary changes of temperature and winds, remaining in the house only on inclement days.

I have frequently known the sponge bath to be taken daily by tuberculous patients, with apparent benefit. It may be safely tried and continued, provided it be followed by an agreeable glow. The temperature of the

water used should be from 64° to 68° Fahr. It is to be borne in mind, with reference to this measure, as well as exercise in the open air, that the susceptibility to attacks of bronchitis is less, the more the exposure, and, also, that an attack of bronchitis does not usually exert any unfavorable influence on the tuberculous disease. Many patients are deterred from going out of doors, when the weather seems unfavorable, by needless apprehension of taking cold. The danger from this source is certainly less than from a deficiency of out-of-door life.

The proportion of cases in which an arrest of the disease is effected is sufficient to authorize the physician to encourage patients strongly to employ the hygienic measures which have been briefly considered. The influence of the disease on the mind is to induce either an expectation of recovery without effort, or resignation to death. It is important to make patients understand that very much depends on their own exertions. One of the great difficulties in the way of successful management is a passive, patient, tranquil frame of mind, which cannot be aroused to vigorous efforts. Persons endowed with resolution, energy, and perseverance, other things being equal, are more likely to struggle successfully with the disease than they who are deficient in these mental qualities. The measures which have been considered, if not successful in effecting an arrest of the disease, tend to retard its progress, and render the condition of patients most comfortable while life lasts.

Change of climate, as a means of effecting a cure of pulmonary tuberculosis, has been a fruitful topic for discussion. It does not fall within the scope of this work to enter into a discussion of this topic. I shall present briefly certain considerations which may be of some practical utility in connection with the question in individual cases, "Shall I try change of climate, and, if so, where shall I go?"

It may be assumed that a change of climate is frequently useful. Granting that in the majority of cases it does not prove successful, there is ample ground for the belief that in not a few cases it is highly beneficial, and it appears sometimes to effect an arrest of the disease. The judgment of patients or their friends, in the matter, is not of much value, because it is usually based on the knowledge of a few cases, or perhaps of a single case, in which benefit may, or may not, have been apparently obtained. Change of climate, therefore, is to be advised under certain circumstances.

It may be taken for granted that there is no specific influence in any climate. It would be therefore quite needless to inquire if there be one particular spot which is to be preferred above all others. Observation shows that different climates are suited to different cases. The qualities which render a climate favorable are elevation, uniformity, and dryness. As regards the latter, the rule is perhaps not without exceptions; some patients appear to do best in situations in which the atmosphere is warm and humid. With respect to temperature, a uniform cold climate is best for some cases, and a uniform warm climate for other cases. Of late years, the custom has been gaining ground of sending patients to a cold latitude, and I have known of a number of instances in which the climate of Minnesota has proved highly serviceable. Were it consistent with the limits of this work, I could cite some cases which are strikingly illustrative of the salutary influence of the uniform, dry, cold atmosphere of that northern region. On the other hand, I have known of numerous instances in which a change to a warm climate has appeared to accomplish all that could be desired. What circumstances, then, are to guide us in deciding whether a cold or warm climate will be likely to prove most advantageous? The feelings and choice of the patient are to have considerable weight. If,

when in health, more vigor and enjoyment are habitually experienced in summer than in winter, a warm climate will probably be best, and, if the reverse be true, a cold climate is to be preferred. The condition of the patient as regards feebleness is an essential point. If he be so feeble as not to be able to live out-of-doors in cold weather, or if the reaction from the impression of cold be slow and imperfect, a warm climate is more suitable. It is rarely proper to send patients to a cold climate if the disease be considerably advanced, and, as a rule, a cold climate is better suited to male than to female patients.

With reference to the particular situation to be selected, it should contain resources for occupation and mental interest. There must be inducements for out-of-door life. I have known patients who had been accustomed to active habits, suffer intolerably from ennui in going to places where the supposed excellence of climate was the only attraction. It is frequently better to move about from one place to another than to remain stationary; as soon as a place becomes tiresome, it is best to leave it. Travelling in foreign countries, without any special regard for climate, is often the best plan, the advantage consisting in the interest and inducements to out-of-door exercise derived from a succession of new scenes. A sea-voyage in warm latitudes is generally useful, and if patients are fond of the sea, a long voyage, if practicable, may be advised. During the past few years many patients under my observation have resorted to sea-voyages; and I can affirm that, while in not a few instances the benefit has been marked, I have never known any harm to ensue. I have known several instances in which patients, in an advanced stage of the disease, the strength being much reduced, have taken long voyages with notable improvement. Places which are especially the resort of patients are to be avoided; the moral effect of seeing daily examples of different stages of the disease is unfavorable. A change is often useful when there is no superiority on the score of climate, because it is in this way only, in certain cases, that relief from the cares and anxieties of business can be secured.

The habits and taste of the patient are to be considered. Persons who are dependent on the associations and comforts of home and friends for their happiness will not be likely to be benefited by being sent away, especially if alone and among strangers. The stage of the disease and the rapidity of its progress are points of great importance. It is truly a cruel act to send to a distance patients who are in a condition admitting of but little prospect of improvement, and who will probably not live to return. The amount of damage which the lungs have sustained, as determined by physical signs, as well as the symptoms, is to be taken into account, before deciding with regard to change of climate. And if a change be made and prove effectual, it becomes an important question whether, if practicable, the change should not be permanent. An arrest of the disease does not extinguish the diathesis, and the safest course, undoubtedly, is to take up a residence in the climate in which the cachexia is less liable to be reproduced than in the climate in which it has been already once developed. Finally, in forming an opinion of the importance of change of climate in the management of this disease, it is to be considered that the progress of the disease will be unfavorable in a large proportion of cases, whatever be the change or changes made; an arrest of the disease is not to be expected save in a small minority of cases. The fact that, of the persons who make trial of change of climate, the number who are not apparently benefited greatly exceeds the number who find this measure either successful or beneficial, should not discourage resorting to the measure so long as in a small proportion of cases it proves effective. Another

consideration is to be added, namely, a change of climate not infrequently appears to retard the progress of the disease, rendering the patient more comfortable and prolonging life, although an arrest of the disease be not effected.

Passing now to consider the remedies which enter into the management, I place under this head alcoholic stimulants, without discussing the question whether they are properly so regarded, or whether, as was claimed by Todd, they are alimentary rather than medicinal. The remedial agency of alcoholics in this disease has given rise, of late, to much discussion, and, on this point, the views of physicians are somewhat divided. Basing my opinion on clinical experience, I do not hesitate to express the belief that, in a certain proportion of cases, alcohol exerts a curative influence. Of the sixty-two cases of arrested tuberculosis which I have analyzed, in fourteen the treatment, irrespective of hygienic measures, consisted exclusively in the use of alcoholic stimulants. In nine of these cases the recovery was apparently complete, the patients remaining well after periods, dating from the time of the arrest, varying between four months and eleven years. Some cases which I have observed seem to exemplify in a striking manner the curative effects of alcoholic stimulants.

Alcoholic stimulants, however, by no means exert a curative influence in all cases. I have known them to be tried and sometimes tried repeatedly in the same case, and their use abandoned because they were found to produce unpleasant effects. The determination of their appropriateness and importance, or otherwise, is thus to be made in each individual case, and based, of course, upon a fair trial. And the question at once arises, what are the circumstances which experience shows to denote their usefulness on the one hand, or their want of usefulness, if not hurtfulness, on the other hand? If the immediate effect be that of a cordial, that is, if they produce a sense of comfort; if they be followed by a feeling of increased strength and a greater disposition to exercise; if they do not excite unduly the circulation or nervous system, benefit may be expected from their use. *Per contra*, if their immediate effect be discomfort; if they be followed by a feeling of increased weakness and less disposition to exercise, and if they excite unduly the circulation or nervous system, they will not do good, and they may do harm.

The quantity to be taken is an important matter. Some physicians, overconfident in the curative power of alcohol, advise their patients, in general terms, to drink as freely as possible. This is to be deprecated as well as the indiscriminate use of alcoholic stimulants. They are to be given sometimes largely, sometimes moderately, and sometimes sparingly. In the previous editions of this work I gave the synopsis of the case of a young girl who took a pint of whiskey daily for two years, an arrest of the disease being apparently effected by this free use of spirit. It would be an erroneous inference from the curative power manifested in such cases, that a large quantity is to be given in all the cases in which this remedy is found to be useful. How are we to be guided in this matter? I will state the rule which experience has led me to adopt. Under the conditions which indicate the use of alcoholic stimulants, they may be given, with reference to a curative influence, as freely as they can be taken without discomfort, without a sense of weakness or indisposition to exertion, and without undue excitement of the circulation or nervous system. The limitation in quantity is to be determined by the same circumstances which indicate their use, or, in other words, by their immediate effects. And, guided by these circumstances, it will be found that some patients will bear a large, some a moderate, and some only a small quantity. This

disease is one of those which, in certain cases, induce a remarkable tolerance of alcoholic stimulants.

The form of alcoholic stimulants to be used is another practical point. In the cases which I have observed, whiskey has been oftenest used. Some have thought that this form of spirit is especially adapted to cases of tuberculosis. I do not join in this opinion. Whatever be the form used, I believe the remedial principle to be alcohol. But no form is equally applicable to all cases. Some patients are benefited especially by spirits, some by wine, and some by malt liquors. Of the different varieties of spirits, wine, and malt liquors, each is best suited to particular cases. The indication for the selection of the form to be used in individual cases must be derived from the preference of the patient and the results of experimental trials.

In conclusion there is an important matter connected with the employment of alcoholic stimulants which, although not pertaining to the consideration of their therapeutical influence, should not be ignored. I refer to a risk of forming habits of intemperance. If their remedial use involve this risk, it becomes a question how far we are warranted in incurring it by their curative power. But in no case in which I have employed alcoholic stimulants has there been developed, so far as I know, a desire for them or a reliance upon them, rendering it difficult to relinquish their use. I have directed my attention particularly to this point, and I have not yet found an instance in which there was any reluctance to discontinue alcoholic stimulants whenever it was deemed advisable. I am not aware that in a single case among the great number in which I have advised the use of alcoholic stimulants has a patient fallen into intemperate habits. I certainly am not prepared to advocate the use of alcoholic stimulants as a prophylactic; that is, to sanction indulgence among those who believe or fancy that they are in danger of becoming tuberculous. I would not advise their use in doubtful cases; it should follow a clear diagnosis based on signs and symptoms. In persons with the unfortunate idiosyncrasy which leads to an irresistible craving on the slightest indulgence, the immediate effects would always contra-indicate their use in conformity with the rules which should govern our practice in cases of tuberculosis. And finally, when employed as a remedy, they are not to be taken as a means of conviviality, or for any other than a curative influence. Observing these precautions, we may expect to secure their remedial agency without exposing our patients to a calamity which, in a moral point of view, would be far greater than a failure to effect an arrest of pulmonary tuberculosis.[1]

With regard to cod-liver oil, the same inquiry arises as with respect to alcoholic stimulants, viz., whether it be proper to regard it as a food or a medicine. Not stopping to discuss the propriety of classing it among remedies, I proceed briefly to consider the practical points connected with its employment in cases of pulmonary tuberculosis. All clinical observers unite in according to it more or less value. Its usefulness in a certain proportion of cases can hardly be doubted. Of the cases of arrested tuberculosis which I have analyzed, in five the treatment consisted exclusively in the use of cod-liver oil and hygienic measures. How much importance is to be attached to an intrinsic tendency, and how much to

[1] These remarks on the use of alcoholic stimulants, and the remarks which follow on the use of cod-liver oil, are, in a great measure, taken from the author's clinical report to the New York Academy of Medicine on the management of pulmonary tuberculosis.

hygiene, in these cases, cannot be determined, but an examination of the circumstances belonging to the individual histories goes to show that a certain amount of curative influence belongs to the oil.

The amount of curative influence which cod-liver oil, or any remedial agent, exerts, cannot be accurately defined, because it is impossible to determine the proportionate amount of influence that may be exerted either by self-limitation of the disease or by hygienic measures, but, practically, this is of less importance than to ascertain whether a remedy possess curative power, be the degree greater or less. If a remedy have considerable influence, it is, of course, more desirable to employ it than if the amount of influence were small; but let the influence be never so small, we are not, on that account, warranted in withholding it in a disease of such gravity as this. Practically, the question of the use or non-use of the oil relates to individual cases. Clinical observation shows that it is not useful in all cases. I shall give, briefly, the rules which my own experience has led me to adopt respecting its use and non-use.

If it be taken without great repugnance, if it do not impair the appetite or digestion, nor occasion derangement of the bowels, it may be expected to do good. If it produce any of the effects just named, its propriety is questionable. It is best to begin with a small quantity and increase to the maximum quantity, which is from half an ounce to an ounce three times daily, taken near the time of meals, either before or after, as choice or experience may dictate.

The hypophosphites were introduced, some years since, by Dr. Churchill as a specific remedy, the pathology of the disease being supposed to involve a deficiency in the system of phosphorus, and this element existing in the hypophosphites in a form readily assimilable and in a low state of oxidation. Experience has abundantly shown that the disease is not arrested by the introduction of phosphorus into the system, in other words, that this has no claim to be considered as a specific remedy; but it appears in some cases to be highly useful as a tonic remedy.

The fusel oil, introduced as a remedy in this disease by Dr. Morrell Wyman, has been employed to a considerable extent in this country, more especially in the New England States, not as a remedy supposed to exert any specific influence, but as affecting favorably the pulmonary symptoms. During a service of three months in the heart and lungs department of the Demilt Dispensary of New York, I prescribed this remedy in a large number of tuberculous cases. In the majority of cases no apparent benefit was produced, but in some instances the patients reported relief as regards the cough and expectoration.

The chlorate of potassa was supposed, by the late Dr. Fountain, to have a special efficacy in this disease. I made trial of this remedy in all the hospital cases received into my wards at the New Orleans Charity Hospital, in the winter of 1860. The cases were fourteen in number. They were at once placed on the use of this remedy, from three to four drachms being taken daily, with no other remedy than a palliative for cough, alcoholic stimulants being generally withheld; and this treatment was continued in each case so long as the patient did not seem to be losing ground. A clinical report of these cases was published in the *American Journal of the Medical Sciences*, October, 1861. The conclusion drawn from these cases, as regards the curative influence of this remedy, is stated in the report as follows: "Of fourteen recorded cases of phthisis in which the chlorate of potassa was given in sufficient doses and for a sufficient period to test its remedial power, in nine the histories afford no evidence of any salutary effect from the remedy; in four cases the circumstances render it

doubtful whether much, if any, influence was fairly attributable to the remedy, and in one case only is there room for the supposition that the remedy was highly beneficial. These cases, therefore, fail to furnish proof of any special efficacy in this remedy to arrest or retard the progress of the disease." This conclusion is not at variance with the opinion that, as a tonic remedy, the chlorate of potassa may be useful in certain cases of the disease.

The different tonic remedies are indicated in this disease. Quinia, the bitter infusions, the infusion of the wild cherry bark, the citrate of iron and quinia, and the different chalybeates, are to be prescribed according to the circumstances belonging to different cases, and frequently in succession in the same case. It has been conjectured that the continued use of iron may favor hæmoptysis. I have never seen any clinical evidence of this, but, if there be ground for the conjecture, the inappropriateness of the remedy does not follow. The fact that tuberculous disease is not often developed in patients affected with anæmia has been supposed to militate against the propriety of chalybeate remedies; but it is manifestly illogical to infer from this fact that the anæmia which is secondary to, and probably an effect of, the tuberculous disease exerts any retarding influence upon the latter. Some eminent French authors oppose the use of iron in cases of pulmonary tuberculosis; but the majority of experienced physicians hold the opinion that chalybeates are often useful, and this opinion is in accordance with my own observations. Other remedies, the value of which is attested by experience, although they have no claim to be considered as exerting a special anti-tuberculous effect, are sulphur, arsenic, and iodine. Sulphur is to be given in small doses, or a trial may be made of the mineral waters containing this element. Arsenic, in minute doses, long continued, is extolled in strong terms by two French writers, M. Isnard and M. Moutard-Martin. Of late, I have prescribed this remedy in a considerable number of cases with manifest advantage. Preparations of iodine have been thought by many to be useful in cases of tuberculosis, as they are undoubtedly in cases of scrofulosis. The chloride of sodium is to be added to the remedies just named. Still another remedy to be enumerated is a solution of caoutchouc in the spirits of turpentine and prepared as a confection. Dr. Theodore R. Varick, of Jersey City, has used this last-named remedy in many cases, as he thinks, with notable benefit. Having at his suggestion made trial of it in a number of patients at Bellevue Hospital, I can bear testimony to its apparent utility in certain cases. It is not a disagreeable remedy, but some patients after a time acquire a repugnance to it.

Certain pulmonary symptoms claim attention. Expectorant remedies, as a rule, are not called for. If they diminish appetite, occasion nausea, or disturb digestion, they do more harm than good. But remedies to allay superfluous cough, that is, cough not required for expectoration, are useful. For this end the succedanea of opium, viz., hyoscyamus, conium, belladonna, and hydrocyanic acid may be prescribed, but, if these prove inefficient, opium in some form is required. Patients should be instructed not to yield to the disposition to cough, but to resist it whenever it is not effective. The habit of coughing unnecessarily is, in a great measure, under voluntary control. Soothing inhalations are sometimes useful in allaying the irritation which excites cough. The vapor of water, or spray, impregnated with conium or opium, may be inhaled. I have known the vapor of chloric ether to be highly useful as a palliative.

I can say nothing of the attempt to inject tuberculous cavities with a solution of the nitrate of silver or other medicated liquids through the

larynx and trachea. Aside from the difficulty of the operation, and the impossibility of limiting the application of the injected liquid to cavities, nothing beyond a palliative effect could be expected from this measure were it ever so successfully executed.

Certain complications furnish indications for treatment. Attacks of dry, circumscribed pleurisy, call for mild revulsive and soothing applications, such as sinapisms, liniments, or the belladonna plaster. Local bleeding by leeches or cups is never required. The pain incidental to these attacks generally passes off in a few days at furthest. The treatment of coexisting laryngitis has already been considered. Diarrhœa, dependent on tuberculous enteritis, is to be kept in check by astringents and opiates, the latter being used with as much reserve as is consistent with the object to be attained. Chronic peritonitis claims only palliative measures. Perineal fistulas should be allowed to continue without surgical interference.

In the progress of the disease, symptoms other than those relating to the chest, require palliative measures. The night perspirations are frequently the source of great discomfort. The mineral acids, especially the dilute sulphuric acid and gallic or tannic acid, frequently afford relief. The external application of an astringent, such as alum dissolved in spirit, is sometimes effective. Dyspnœa may be mitigated by ethereal preparations.

A comparison of the measures of management now generally pursued in this disease with the measures in vogue a quarter of a century ago, shows a complete and radical change. Formerly, general and local bloodletting, cathartics, emetics, mercurials, counter-irritation, low diet, and confinement within doors were sanctioned by teachers and writers, and entered, more or less, into the treatment usually adopted. At the present time, the measures which are most approved are, in all points, the reverse. The latter are based on more correct pathological views, and the results of clinical observation. It is not unreasonable to hope that, at some future time, a remedy or remedies may be discovered, capable of exerting a special influence over the disease, but, in the mean time, reliance is to be placed on an early diagnosis, the employment of remedies which, directly or indirectly, may exert, to some extent, a curative influence, and, above all, the hygienic measures which tend to invigorate and strengthen the system.

Acute Pulmonary Tuberculosis.

The distinction between *rapid* and *acute* tuberculosis has already been stated. In rapid tuberculosis the disease runs its course speedily, the accumulation of the product, softening, ulceration, and the formation of cavities taking place within a few weeks. Cases of the acute variety differ in this: the tuberculous product is in the form of small, distinct, round tubercles, called from their size miliary, which accumulate in immense number, and life is quickly destroyed by the interference with the function of respiration, and a high degree of constitutional disturbance. The miliary tubercles, in cases of so-called acute phthisis, may consist of the yellow tuberculous product, or they are the semi-transparent bodies distinguished as the gray tuberculous product. The accumulation of these bodies in immense number characterizes cases of so-called acute phthisis. It is a question whether these two products are pathologically distinct, or whether the yellow are the gray tubercles which have undergone a cheesy metamorphosis. However this may be, the distinctive fea-

ture of the form of pulmonary tuberculosis now under consideration is the rapid accumulation of miliary tubercles, and a fatal termination without tuberculous infiltration or the coalescence of the tubercles forming masses which liquefy and lead to the formation of cavities.

Cases of acute pulmonary tuberculosis present striking points of difference, as compared with the usual chronic form of tuberculosis, not only in respect of duration and the appearances found after death, but as regards the physical signs, and the symptoms belonging to the clinical history. The readiest way of presenting a general view of this rare form of disease will be to give a synopsis of a few illustrative cases.

Case 1. Miss C., aged 32, daughter of an eminent physician, while away from home on a visit of pleasure, considering herself well, was attacked in the night with hæmoptysis. It was at first slight, but recurred twice during the same night, and was considerably profuse. I saw her ten days afterward. In the mean time she had kept the bed, the respirations had been accelerated, the prolabia had been livid, the pulse frequent, and she was greatly prostrated. When I saw her, these symptoms continued, the respirations being 36 per minute, the pulse varying from 120 to 130, the cough and expectoration slight. She died the following night, eleven days after the occurrence of hæmoptysis. She had had a slight hæmoptysis six years before, and subsequently had been subject to a slight cough, but there had been no notable diminution in weight, and she had always considered herself well.

An examination after death was made by the attending physician, Dr. Walter Carey, of Buffalo, who stated that he found old pleuritic adhesions on both sides, and both lungs stuffed with miliary tubercles, which he described as hard and semi-transparent; there was no aggregation of tuberculous matter into masses, and there were no cavities.

It is fair to conclude that in this case either the formation of miliary tubercles, or granulations, commenced at the time of the hæmoptysis, or, if they existed previously, they were comparatively few in number, but rapidly accumulated from that time, destroying life in so short a period as eleven days.

Case 2. In November, 1860, I examined a slave-girl, aged 18, in an infirmary, at New Orleans, under the charge of my colleague, Prof. Beard. She was at that time apparently convalescing from typhoid fever, and a careful exploration of the chest disclosed no signs of pulmonary disease. She seemed to be slowly convalescing, when, about the first of January, 1861, a violent cough occurred, the pulse became frequent, she lost weight and strength rapidly, and died in about six weeks. On examination after death, the lungs were free from adhesions, but crammed with small, hard bodies, not larger than pins' heads. Both lungs were about equally crammed. The spleen and liver contained the same bodies in great numbers, and the peritoneum was studded with them. Hæmoptysis did not occur in this case, and the expectoration was slight.

Case 3. A male patient, the age not noted, was admitted into the Charity Hospital of New Orleans, in the service of my colleague, Prof. Fenner, February, 1861, and died on the third day after his admission. When admitted, he declared he was perfectly well at the time he was attacked with his existing disease, which was five weeks before his admission. His symptoms were cough without expectoration, accelerated breathing and dyspnœa, lividity of prolabia, and frequency of the pulse. He was examined by one of my private pupils, who found everywhere a clear resonance on percussion, and abundant subcrepitant rales.

After death, the lungs, which were placed at my disposal, were found

to contain an immense number of miliary tubercles, of about the size of a pin's head, not hard and semi-transparent, but opaque and cheesy. At the apex of the right lung was a cavity of about the size of an English walnut, anfractuous, empty, and lined by a smooth serous-like membrane. Another small cavity existed near the apex of this lung. Near the apex of the left lung was a cavity of the size of a common American walnut, not anfractuous, but also empty, and lined by a serous-like membrane. The miliary tubercles were less abundant at the summit than in the middle and inferior portions of the lungs.

This case affords an illustration of one of the modes in which pulmonary tuberculosis ends favorably, viz., in dry, innocuous cavities. The miliary deposits were undoubtedly of recent date, and were sufficient to destroy life without the processes of aggregation, softening, and excavation.

The diagnosis in cases of acute pulmonary tuberculosis may be attended with difficulty. If hæmoptysis do not occur, and the pulmonary symptoms be not marked, the existence of thoracic disease is liable to be overlooked, and the patient may be supposed to have typhoid fever. This error in diagnosis has been repeatedly made. Delirium sometimes occurs, and this tends to obscure the diagnosis. A careful examination, however, should lead to the conclusion that there is some grave affection within the chest, and typhoid fever is to be excluded by the absence of the characteristic symptoms which belong to the clinical history of that disease. But having decided that the disease is seated within the chest, the diagnosis is still not altogether easy, because physical signs do not point directly to the nature of the affection, and analogous symptoms belong to several thoracic affections, viz., capillary bronchitis, pneumonitis, pleuritis, and certain affections of the heart. The signs of the disease are not positive, for, the tubercles being minute and discrete, and, moreover, existing equally in both lungs, exploration of the chest may furnish no marked disparity in the resonance on percussion, and none of those modifications of the respiration and voice which denote pulmonary solidification. The diagnosis is to be made, so far as physical signs are concerned, mainly by exclusion. Pneumonitis, pleuritis, and diseases of the heart, may be readily excluded by the absence of the signs of those affections. Capillary bronchitis is not so readily excluded, but this affection generally supervenes on an attack of ordinary acute bronchitis; it runs a more rapid course than acute tuberculosis, and, if it end fatally, presents a much greater violence of pulmonary symptoms, especially dyspnœa.

Unhappily, the treatment of acute pulmonary tuberculosis may be dismissed with a very few words. The condition of the patient is hopeless, and all that the physician can do is to palliate symptoms and support the powers of life.

SECTION SECOND.

DISEASES AFFECTING THE CIRCULATORY SYSTEM.

CHAPTER I.

Introductory Remarks. Pericarditis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Chronic Pericarditis. Pneumo-Pericarditis.

DISEASES affecting the circulatory system are seated in the blood, the bloodvessels, and the central organ of the circulation—the heart. The morbid conditions of the blood, so far as they are at present known, are, in general, either common to different individual diseases, or they are involved in affections which are distributed in other nosological divisions. The consideration of these conditions, therefore, belongs to general, rather than special, pathology, and they have been considered in the first part of this work. Diseases of the vessels—the arteries and veins—are fully considered by surgical writers, entering, as they do, much more largely into maladies which belong to the surgeon, than into those which fall within the province of the physician. Of the affections of the arteries, aneurisms situated within the chest and abdomen will alone claim attention in this treatise. Thoracic aneurisms will be noticed in this section; those situated within the abdomen will be referred to in connection with abdominal tumors, in the next section. Inflammation of the veins (phlebitis) has been referred to in connection with purulent infection of the blood. This section will be devoted chiefly to diseases affecting the heart.

The clinical study of the diseases of the heart has been prosecuted with much success within the past few years, and, perhaps, in no other department of medicine is the recent advancement of practical knowledge more conspicuous than here. This is, in a great measure, due to the successful employment of physical exploration in the diagnosis of these diseases. The discrimination of these diseases by means of the signs derived from the application of percussion and auscultation, has been brought to great perfection by the researches of Bouillaud, Hope, Stokes, and others. It does not come within the scope of this work to treat fully of the signs involved in the diagnosis of cardiac affections. For this important information the student and practitioner are referred to treatises devoted specially either to diseases of the heart, or to the physical exploration of the chest. I shall content myself here, as in treating of pulmonary affections, with a brief account of the phenomena determined by percussion and auscultation.

The diseases of the heart are conveniently arranged in the following groups: 1. Inflammatory affections. 2. Structural lesions. 3. Functional disorder. I shall consider them in this order, and the present chapter will be devoted to one of the inflammatory affections. Inflammation affecting the heart gives rise to different affections according to the

structure in which it is seated. Inflammation of the serous membrane investing the heart, or the pericardium, is one affection, called *pericarditis*. Inflammation of the membrane lining the cavities of the heart, or the endocardium, is another affection, called *endocarditis*. Inflammation of the substance of the heart, or the muscular walls, is distinguished as *myocarditis*. These three inflammatory affections claim separate consideration.

Acute Pericarditis.

Pericarditis occurs as an acute and a chronic affection. Acute pericarditis will be now considered, and, afterward, the chronic form of the disease.

Anatomical Characters.—The morbid appearances resulting from acute inflammation in this situation are essentially the same as in other serous membranes when inflamed, for example, the pleura. Exudation of fibrin or lymph takes place in more or less abundance, commencing shortly after the development of the inflammation. The lymph is disposed in the form of a layer, or a series of layers, on the visceral and the parietal surface of the membrane. It is at first soft and easily removed, but becomes dense and closely adherent in proportion as it is of old date. The movements of the pericardial surfaces frequently cause the lymph to assume a reticulated or areolated appearance, or it is disposed in masses, and it is sometimes in the form of numerous filaments or villous projections giving to the surface a shaggy aspect. The vessels beneath the membrane may be congested, giving rise to arborescent redness, and spots of ecchymosis are sometimes observed. Different cases differ greatly as respects the quantity of lymph, and the extent of surface covered by it, as well as the appearances caused by the different modes in which it is disposed. The presence of lymph, here, as in other serous inflammations, is essential as proof of the existence of pericarditis.

More or less liquid effusion usually takes place, as in other serous inflammations. The effused liquid is serum, turbid from the admixture of lymph, and it contains, usually, flakes or shreds of lymph in greater or less abundance. The presence of a purely serous liquid within the pericardial sac, that is, without lymph, is not evidence of inflammation; it is a dropsical, not an inflammatory, effusion. The quantity of effusion in different cases of pericarditis varies greatly, amounting, in some cases, to a few ounces only, and in other cases to a pint or more. The liquid is sometimes, but very rarely, purulent. It is sometimes sanguinolent.

If the disease progress favorably, the effused liquid is reabsorbed, and the pericardial surfaces, then coming into contact, are agglutinated by means of the intervening lymph. If recovery take place, the lymph is slowly absorbed; adventitious tissue becomes developed, leading to permanent adhesion of the pericardial surfaces. The adhesion by means of the newly-formed tissue may be limited to portions of the heart, and then the surfaces may become connected by bridles or bands which are sometimes drawn out to a considerable length; or, the adhesion may extend over a quarter, a half, or three-fourths of the organ; or, the surfaces may be everywhere united, the sac being completely obliterated. The latter is the most frequent result of acute pericarditis.

The most convenient mode of dividing the disease into stages is the same as that adopted in pleuritis. The first stage extends to the time when effusion takes place to an extent sufficient to be appreciated by the

physical signs. The second stage, or the stage of effusion, continues until the liquid is absorbed. The third stage extends from the absorption of the liquid to the recovery, and this is, generally, the stage of convalescence.

Clinical History.—The symptoms present in cases of acute pericarditis are almost invariably made up, to a greater or less extent, of those arising from coexisting affections, for, in the great majority of cases, the disease is associated with either articular rheumatism, Bright's disease of the kidneys, or pleuritis with or without pneumonitis. Under these circumstances, it is not always easy to determine to what extent certain symptomatic phenomena are due to the cardiac affection. As a rule, the development of the inflammation is attended with more or less pain which, in some cases, is acute and lancinating, like the pain in pleuritis, and increased by forced breathing, so that the disease has not infrequently been supposed to be inflammation of the pleura. The intensity of the pain varies much in different cases; it is by no means always a prominent symptom, and it is sometimes slight or wanting. A dry, irritable, suppressed cough is generally present. Tenderness over the præcordia is more or less marked, and pressure in the epigastrium upward in a direction toward the heart, sometimes occasions acute pain. The pain produced by a deep inspiration may cause the patient to shorten this act, and, hence, the number of respirations per minute is increased. The *alæ nasi* may dilate in inspiration. Patients sometimes manifest suffering from an indefinite sense of distress, without acute, localized pain, and, in females, hysterical phenomena may be associated with the development of the disease. The action of the heart is increased, amounting, sometimes, to palpitation. The pulse is more or less accelerated, quick, and vibratory. The usual concomitants of febrile movement, viz., anorexia, debility, etc., are present. These are symptoms belonging to the first stage.

The duration of the first stage is usually short. An appreciable amount of effusion may take place in a few hours, and it is rarely delayed beyond one or two days. The acuteness of the local symptoms, viz., pain and soreness, then diminishes, and, if the amount of liquid effused be sufficient to fill or distend the pericardial sac, symptoms are added which proceed from the pressure of the liquid upon the heart. These symptoms are, a sense of oppression referable to the præcordia; a tendency to syncope on exertion, which leads the patient to refrain as much as possible from movements of the body; feebleness and irregularity of the pulse, with a notable increase on emotional excitement or any muscular effort; dyspnœa, sometimes amounting to orthopnœa, if the accumulation of liquid be large and rapid; feebleness of the voice, and dysphagia, in some cases, produced either by pressure of the distended sac on the œsophagus, or as a neuropathic concomitant. Vomiting is an occasional symptom. Some cases are characterized by remarkable disturbance of the nervous system. Mental aberration, consisting in obstinate taciturnity and indifference, alternating with paroxysms of maniacal excitement under the influence of delusions which excite terror, is occasionally observed. Coma and tetanic convulsions have been known to occur. These symptoms are apt to mask the cardiac disease, and lead the practitioner to suspect disease of the brain. Autopsical examinations show that, in these cases, neither inflammation nor any appreciable lesions of the nervous system exist, and, hence, the phenomena are to be referred to functional disturbance of the nervous system.

The severity of the disease, as denoted by the symptoms, corresponds

to the intensity of the inflammation and the amount of effusion. If the inflammation be slight or moderate and the quantity of effused liquid small, the disease may run its course without any symptoms denoting gravity, and the symptoms may not even point to the existence of any affection within the chest. In other cases it is one of the most distressing and formidable of diseases. The symptoms due to compression, of course, diminish as the liquid is absorbed. The absorption sometimes goes on very rapidly, and, in this respect, different cases present great variation. If, instead of being absorbed, the liquid continue to accumulate, and life be not rapidly destroyed, the pericardial sac may become greatly dilated, and the affection becomes chronic. The rapidity and completeness of recovery after absorption will depend on the amount of lymph which has exuded. This may be too abundant to be absorbed, and the disease may end fatally after continuing for a greater or less period in a chronic form. In cases which go on favorably toward recovery, the action of the heart is apt to be feeble and easily excited during the stage of convalescence.

Pathological Character.—Acute pericarditis does not differ essentially in character from other serous inflammations. The same series of processes which take place in the serous inflammation considered in the preceding section (pleuritis) occur in this inflammation, viz., exudation and liquid effusion, agglutination followed by permanent adhesion of the free surfaces of the membrane, and sometimes the formation of pus. Suppurative pericarditis, however, occurs in a smaller proportion of cases than suppurative pleuritis, or empyema. As in cases of pleuritis and other serous inflammations, so in different cases of pericarditis, both the actual and relative amount of lymph and serum differ greatly. In some cases, the quantity of lymph exuded is small and the effusion of liquid is abundant; in other cases, the lymph is abundant with but little liquid, and, again, in other cases, both lymph and liquid are either abundant or small. Judging from the number of cases which I have seen, *dry* pericarditis, that is, the presence of lymph without serous effusion, is not extremely rare.

Causation.—Acute pericarditis may be produced traumatically by perforating wounds of the chest, or contusions. In one of the cases which I have observed, it was produced by a wound inflicted by a one-tined fork. Walshe refers to a case in which the pericardial sac was perforated in the juggler's trick of swallowing a sword, and fatal pericarditis induced. In the Museum of Bellevue Hospital is a remarkable specimen, in which a set of false teeth is contained within the pericardial sac. The teeth were swallowed during profound intoxication, and, lodging in the lower part of the œsophagus, produced ulceration through this tube and into the pericardium, giving rise to fatal pericarditis.

Exclusive of its traumatic origin, the disease is almost always secondary, and is developed in the course of acute articular rheumatism oftener than in connection with any other affection. Occurring in the course of rheumatism, it is distinguished as rheumatic pericarditis. It would appear, from statistical reports, to occur in cases of acute rheumatism in a proportion of about one to six. According to the statistical researches of Bamberger, of 100 cases of pericarditis in about 30 the disease is rheumatic.[1] Generally it is developed in the early part of rheumatism, after more or less of the joints have been affected, but occasionally, the pericarditis precedes the articular affection. When it follows the affection of the joints, it is

[1] Niemeyer, *op. cit.*

not due, as was formerly supposed, to a metastasis of the articular affection, but it proceeds from the same morbid condition which underlies the latter; in other words, both are effects of a common internal cause, supposed to be the presence of lactic acid in the blood. Rheumatic pericarditis is almost always, if not invariably, associated with endocarditis.

Next in frequency to its development in the course of rheumatism, it occurs in connection with either acute or chronic disease of the kidneys. It is not very infrequent in cases of chronic Bright's disease, and is an occasional concomitant of the renal affection which follows scarlatina, and in other cases of so-called acute albuminuria. Under these circumstances, its causation is imputed to the accumulation of urea in the blood.

Pyæmia, scorbutus, the continued and eruptive fevers, erysipelas, and influenza, are other affections in connection with which this disease has been observed to occur, the pathological relation, probably, being the same as when it occurs in connection with rheumatism and renal affections, viz., a common causative condition pertaining to the blood being involved. It is a tolerably frequent concomitant of pleuritis and pneumonitis, affecting either the right or left lung—oftener the latter. And in this connection, it is generally attributed to an extension of the inflammation from the pleura to the pericardium in consequence of the proximity of these membranes. But here, too, it is more rational to refer the pleural and pericardial inflammation to a common internal causative condition, than to suppose the latter to be dependent on the former.

Idiopathic, spontaneous pericarditis is one of the rarest of diseases. I have, however, met with a few examples, or, at all events, cases in which a careful examination failed to discover any pre-existing or coexisting disease, nor was any other affection developed, so long as the patients remained under observation, the period extending only to the time when they had recovered sufficiently to leave the hospital. The extreme infrequency of such cases renders it almost certain that, whenever pericarditis exists, some one of the affections just named will be found associated with it.

Diagnosis.—The events belonging to the clinical history of acute pericarditis are not sufficiently diagnostic for the disease to be discriminated by the symptoms alone, from pleuritis, pneumonitis, or pleurodynia. Its coexistence with the two former of these affections could not be ascertained, and its existence would surely be overlooked in the cases in which the symptoms are but little marked. The diagnosis must rest on physical signs. The presence of lymph gives rise to an adventitious sound or murmur, caused by the rubbing together of the pericardial surfaces in the movements of the heart. The development of this sign is proof of the existence of pericarditis; and, as the exudation of lymph takes place usually within a few hours after the commencement of inflammation, the sign becomes available for diagnosis at an early period of the disease. The sign is called the *pericardial* or *cardiac friction murmur*, or sometimes, in contradistinction from the murmur produced by blood-currents within the heart, an *exocardial murmur*.

The friction murmur is to be distinguished from the murmur produced within the heart, called *endocardial* or *bellows murmur*, by attention to the following points: It is generally double, that is, consisting of two adventitious sounds for each beat of the heart, one produced by the systolic and the other by the diastolic cardiac movements. The character of the murmur frequently denotes friction; that is, it is rubbing, grazing, or grating, and, at a later period in the disease, may be creaking, like the

sound of new leather. It is generally limited to the præcordia, not propagated beyond the borders of the heart, and it may be limited to a portion of the præcordial space. As regards its intensity or loudness, it differs much in different cases, and it is apt to fluctuate in the same case within the time the examination is continued, varying with the force of the heart's action. It has not the same fixed connection with the normal heart-sounds as the endocardial murmurs; in other words, it does not observe the same regularity in rhythm as the latter murmurs. This is a striking point of distinction, provided the auscultator be practically conversant with the endocardial murmurs. It is intensified and sometimes changed in character by firm pressure with the stethoscope.

A friction murmur, if ever wanting in the first stage of pericarditis, is present so generally that we are warranted in basing an exclusion of the disease on its absence, provided sufficient time has elapsed for inflammatory exudation, and limiting the question of diagnosis to the first stage. The production of the murmur is almost pathognomonic, taken in connection with the symptoms and history; yet there is one source of fallacy, viz., the production of a friction murmur by the attrition of the outer surface of the pericardial sac with the pleural surface in cases of pleuritis. A friction murmur produced by the heart's movements, continuing while the patient's breathing is voluntarily suspended, may be thus produced irrespective of pericarditis. Examples have been reported by Addison, Stokes, and others. I have met with several cases, the absence of pericarditis, notwithstanding a well-marked murmur with cardiac rhythm, being determined by examination after death. This variety of the sign is called a *cardiac pleural friction murmur*. It is to be suspected, if pleuritis be known to exist, with or without pneumonitis (oftener the latter), when the murmur is limited to the border of the heart, the intensity of the murmur varying much more than the ordinary cardiac murmur during the periods of examination, it being limited, in some cases, to the end of inspiration, and generally affected more or less by the respiratory movements.

In the second stage, the occurrence of liquid effusion and its amount are determined by percussion. Abnormal dulness exists over an increased area in the præcordial region. The pericardial sac, if it be filled with liquid, forms a pyramidal tumor, the boundaries of which are readily found by percussion. The base of the triangular space is situated below the level of the apex-beat in health; the left border is without the left nipple, and the right border between the right margin of the sternum and the right nipple; the apex is near the sternal notch. The situation, size, and shape of the area of dulness denote pericardial effusion. If the pericardial sac be partially filled with liquid, the area of dulness in the præcordia is abnormally widened at and below the apex of the heart, the widening extending more or less upward in proportion to the quantity of effusion; vocal resonance is diminished within the area of dulness, and also vocal fremitus. If the sac be distended with liquid, the præcordia may be abnormally prominent and the intercostal depressions abolished, as in pleuritis, within this region. Mensuration will show the increased size of the præcordia. The extent of dulness at different periods of the disease will show, on the one hand, progressive increase, or, on the other hand, diminution of the quantity of liquid, and its complete removal.

The friction murmur either diminishes or disappears after considerable effusion of liquid has taken place. Not infrequently it continues, although the pericardial sac be filled with liquid and even much dilated. Under these circumstances, it may be sometimes heard when the patient is raised

to the sitting posture, and disappears when the patient lies on the back. If it have disappeared or been diminished during the stage of effusion, it will be likely to return, and may be more strongly marked, after the absorption of the liquid; and it then persists until agglutination of the pericardial surfaces takes place. Occasionally it continues during convalescence and after apparent recovery.

The apex-beat of the heart, which, in the first stage, is in most cases abnormally strong, is weakened and may be suppressed by the presence of liquid. If the accumulation of liquid be considerable, the situation of the beat is altered; it is raised to the fourth intercostal space and carried to the left as far as, or even beyond, the nipple. The sounds of the heart are weakened by the presence of liquid, especially the first sound, and this sound becomes short and valvular like the second sound.

By means of the signs which have been briefly considered, the diagnosis of pericarditis is generally made without difficulty. Bearing in mind the frequency of its occurrence in articular rheumatism, the practitioner should not omit daily examinations of the chest in cases of rheumatism, with reference to the signs of this complication. The fact that it occurs pretty often in cases of Bright's disease should also be borne in mind; in fact, it is a good rule, in examining a patient with any disease, not to omit an exploration of the præcordia. Developed in connection with pleuritis or pneumonitis, it is apt to be overlooked, and the diagnosis involves more difficulty than when it occurs in other pathological connections. The determination of pericardial effusion, if a large effusion also exist in the left pleural sac, is not always easy, and the chief reliance in such a case must be on the presence of a friction murmur which is believed to be produced, not without, but within the pericardial sac. The occurrence of delirium, coma, etc., in some cases of pericarditis, masks the symptoms pointing to the latter. An examination for the signs of pericarditis should not be omitted in cases presenting notable disturbance of the nervous system.

Prognosis.—Acute pericarditis is in some cases a very distressing and dangerous disease, but in other cases comparatively mild, and, as regards immediate danger, trivial. The gravity depends much on the intensity of the inflammation, the amount of exudation of lymph, and more especially the quantity of liquid effusion, together with the rapidity with which it takes place. A large quantity of liquid, rapidly effused, may lead quickly to a fatal termination. Death, in such cases, is produced by paralysis of the heart from compression, and cases have occurred in which life was destroyed in this way after the lapse of a few hours only from the time of the attack. Generally, however, the duration of the disease, in fatal cases, is from one to two weeks, and death is produced by slow asthenia. In such cases, the immediate cause of death is either the prolonged compression of the heart by liquid, or weakening of the heart's action as a direct effect of the inflammation on the muscular fibres, or both causes combined. Sudden death, by syncope, is liable to be produced by muscular exertion, especially if there be much liquid effusion. In my work on diseases of the heart, I have cited a case in which a patient under my observation, affected with mild pericarditis, died instantly on getting out of bed to go to stool.

But the fatality in cases of acute pericarditis is due, not so much to the disease *per se*, as to coexisting affections. In fact, exclusive of the accidents just referred to, the disease in itself tends intrinsically to recovery. The danger varies greatly with its different pathological connections. Rheumatic pericarditis, not associated with pleuritis or pneumonitis, is

rarely fatal. On the other hand, pericarditis developed in the course of Bright's disease proves fatal in a very large proportion of cases. This difference is explained by the difference as regards gravity between the latter and rheumatism, the ability of the system to sustain any important intercurrent affection being widely different in these two diseases. Cases in which the pericarditis occurs as a complication of pleuritis or pneumonitis show a large rate of fatality. Traumatic cases generally end in recovery, provided the heart be not injured. Occurring as an idiopathic affection and uncomplicated, the prognosis is favorable.

If the disease do not prove fatal during its acute course, it either ends in recovery, or it becomes chronic. Chronic pericarditis will claim separate consideration. In the cases which end in recovery, the usual result is adhesion, by the intervention of newly-formed tissue, of the pericardial surfaces over the whole or the greater part of the organ. In a small proportion of cases, the adhesion is limited to a few small spaces. Occasionally, patches of either false or true membrane, without adhesion of the two surfaces, are the only permanent effects of the disease. It is doubtful if complete absorption of the effused lymph ever take place, leaving no adventitious tissue nor any traces of the disease.

Treatment.—The widely different circumstances under which acute pericarditis occurs must, of course, be taken into account in considering the treatment. The question as to the propriety of bloodletting and other measures heretofore distinguished as antiphlogistic, can only be entertained in the first stage of the disease, and when it is idiopathic, or traumatic, or connected with rheumatism. These measures are undoubtedly inappropriate when the disease is developed in the progress of Bright's disease, or when it is secondary to pleuritis or pneumonitis; in general terms, the propriety of these measures admits of consideration only when the pericarditis is either primary, or secondary to affections which do not in themselves impair considerably the ability of the system to sustain an additional disease. And when not associated with other diseases which are in themselves dangerous, it is to be borne in mind that pericarditis intrinsically tends to recovery.

In the cases to which bloodletting must be limited, the same general principles are to govern its employment, as in other acute inflammations. These principles have been considered.[1] Some importance, perhaps, belongs to this consideration, viz., by diminishing the mass of blood, the heart is less excited, and its labor diminished. On the other hand, it is to be considered that the danger incident to the disease is mainly from paralysis of the heart or impairment of its muscular power. Giving due weight to the latter consideration, bloodletting should be employed with great circumspection, even in the few cases in which the symptoms relating to the circulation, in the first stage of the disease, may appear to indicate it. It is never indicated after considerable effusion has taken place.

Depletion by means of saline purgatives, with restricted diet, is indicated, in the first stage, by the same symptoms as in other acute inflammations. This remark is alike applicable to nauseant and other sedatives. These should be limited to the first stage. They might be pernicious if continued after effusion has occurred, and, hence, the great importance of determining the presence of liquid and its amount, by physical signs.

Shall the system be brought under the influence of mercury in the first stage? This is a question which different writers and practitioners answer

[1] *Vide* page 148.

quite differently, some advocating rapid mercurialization as highly important, others regarding it as needless and hurtful. In the cases in which mercury is by some considered important, and by many admissible, my experience leads me to be satisfied to forego its use.

Opium is invaluable in this, as in other acute inflammations. It is indicated by pain and constitutional disturbance, and is to be employed sufficiently to relieve the general and local symptoms. The form of opiate and the mode of administration are to be determined by the circumstances in individual cases. The hypodermic method in this, as in various other affections, is eligible and efficient.

Locally, mild, revulsive, and soothing applications are useful in the first stage. Sinapisms, a poultice, the water-dressing, or the spongiopiline saturated with a warm anodyne infusion, may be employed. Blisters in this stage should not be employed. Aside from their interference with the daily physical explorations, which are vastly important, they do more harm, by adding to the pain and constitutional disturbance, than good by way of revulsion. By some German writers cold applied to the præcordia, as in the treatment of acute pleuritis and pneumonitis, is said to be useful. The evidence of its usefulness is the relief of pain, together with diminished frequency of the heart's action.

The indications in the second stage relate, *first*, to the liquid effusion. If the amount of effusion be sufficient to enfeeble the heart by compression, it is highly important to effect the removal of the liquid as speedily as possible. For this end, the præcordia may be painted daily with the tincture of iodine, and small blisters may be applied, removing them as soon as vesication begins, and allowing the blistered surface to dry up rapidly. Hydragogue cathartics and diuretics may be employed, as in pleuritis, taking care not to carry these measures so far as to depress the vital powers and weaken the heart's action. This causation is of great importance, and it suggests a *second* indication which may be present in the second stage, viz., to strengthen the heart's action, and support the powers of life, by the timely and judicious use of alcoholic stimulants, tonics, and nourishment. Keeping in view the fact that the disease, if it end fatally, destroys life by affecting directly the heart's action, the measures just named are indicated with an urgency proportionate to the degree of feebleness of the circulation. All measures which tend directly or indirectly to weaken the circulation or depress the vital powers, are contraindicated in the second stage. The liability to fatal syncope on exertion is to be borne in mind, and quietude should be rigidly enjoined. Feebleness and irregularity of the pulse in the second, and sometimes in the first, stage, constitute an indication for digitalis, which, however, should not be given sufficiently to retard unduly the heart's action.

During the stage of convalescence, precautions against undue excitement of the action of the heart by exercise, mental emotions, over-repletion of the stomach, etc., are more important than during recovery from most other acute inflammations. At the same time, convalescence will be expedited and complete recovery secured, by a nutritious diet, tonic remedies, gentle gestation out of doors, and other hygienic measures to promote speedy recuperation.

In the treatment of pericarditis developed in the course of either rheumatism or renal disease, it may be important to take into account the supposed presence in the blood of a morbid material upon which the pericardial inflammation depends. The indication derived from this view of the causation is, in general terms, to remove, if possible, the continued operation of the cause, by measures addressed to the morbid conditions

of the blood belonging to those affections. This part of the treatment, however, will be more appropriately considered in connection with rheumatism and renal disease hereafter. The importance of measures to prevent the development of pericarditis, in the course of these diseases, will also be then considered.

If the disease end in recovery, without becoming chronic, adhesion of the pericardial surfaces, to a greater or less extent, may be expected to take place. This result was formerly supposed, by Hope and others, to lead to progressive enlargement of the heart, and therefore pericarditis was regarded as a highly serious disease with reference to its remote effects. This is an error which arose from imputing to pericardial adhesions the consequences of the valvular lesions which often coexist. It may be doubted if adhesions alone tend to produce enlargement, and there is reason to believe that, if not associated with valvular lesions, they may give rise to little or no inconvenience. The pericardial surfaces are not infrequently found, in autopsical examinations, universally adherent, as a result of ancient pericarditis, without any other evidence of cardiac disease, and when no symptoms referable to the heart had existed during life.

Chronic Pericarditis.

Chronic pericarditis may be subacute from the beginning, or it may follow the acute form of the disease. If acute pericarditis do not end in convalescence after the lapse of from two to three weeks, it becomes a chronic affection. As regards anatomical characters, cases differ. In some cases of chronic pericarditis, there is no liquid effusion, but the pericardial surfaces are agglutinated by several layers of lymph, which collectively may be half an inch or more in thickness. Under these circumstances, the lymph is not absorbed, a low grade of inflammation continues, and the disease ends fatally after a variable duration.

In other cases, liquid effusion remains and progressively accumulates, the pericardial sac becomes more or less dilated, and it is sometimes so much enlarged as to depress the diaphragm and occupy the greater part of the thoracic space. The amount of liquid which has been known to accumulate in the pericardium is enormous, amounting to eight or ten pints.

In chronic pericarditis without liquid effusion, pain is rarely prominent. The symptoms are those dependent on feebleness of the circulation, due to the impaired muscular power of the heart, and on constitutional irritation. In the cases in which large effusion exists, the heart is weakened by compression, and the patient suffers from dyspnœa caused by interference with the respiratory function. The dyspnœa may amount to orthopnœa if the accumulation of liquid be very large. Pain under these circumstances is rarely a prominent symptom.

The diagnosis, if liquid effusion be not present, must often be inferential, being based mainly on the knowledge of the existence of antecedent acute pericarditis. Creaking friction-murmur exists in some cases, notwithstanding the agglutination of the pericardial surfaces. If friction-murmur be not present, and acute pericarditis be not known to have existed, a positive diagnosis is extremely difficult, if not impossible. The heart is found to be more or less enlarged, but there are no means of determining that the enlargement proceeds from the deposit of lymph. If liquid effusion be present, the physical signs render the diagnosis easy and positive. Flatness on percussion exists on the anterior surface of the chest, extending on either side of the sternum toward the axillary

region, in proportion as the pericardial sac is dilated. Obliteration of the intercostal depressions and even bulging may be observed. Fluctuation in the intercostal spaces is sometimes felt. Laterally, beyond the limit of the flatness on each side, resonance on percussion and the respiratory murmur show the presence of lung. The heart's impulse is suppressed, but a shock communicated by the action of the heart may be felt. A friction-murmur is sometimes heard, even when the quantity of effused liquid is very large. The sounds of the heart are feeble, the first sound being more weakened than the second, and short and valvular like the second sound. These signs render the diagnosis sufficiently clear.

The prognosis in cases of chronic pericarditis is always extremely unfavorable. The disease ends fatally after a duration varying much in different cases.

The indications for treatment are to improve the tone of the system and impart vigor to the heart by tonic remedies, together with nutritious diet and other hygienic measures. The propriety of much counter-irritation is doubtful. Everything which tends, directly or indirectly, to weaken the heart or the vital powers is to be avoided. In this point of view, mercurialization is objectionable. If there be much liquid effusion, diuretic remedies may be tried, and small blisters. Hydragogue cathartics, in these cases, if the patient be feeble, are to be employed with great circumspection. In a case under my observation, elaterium given in small doses and producing but a moderate effect, appeared to hasten the fatal termination. Iodine may be employed as a sorbefacient, externally and internally. Puncture of the pericardial sac is admissible, if the effusion be large and other measures fail to diminish it. Clinical data for determining the value of the operation of paracentesis are wanting.

Pneumo-Pericarditis.

This name denotes the presence of air or gas within the pericardial sac in cases of pericarditis. Air or gas may find its way into this situation through a wound of the thoracic walls, or of the œsophagus, and through a fistulous communication between the lungs or the stomach and the pericardial cavity. Air may get access into this cavity through a wound of the chest, and pericarditis not be developed. The condition, then, is expressed by the term *pneumo-pericardium*. It is possible that gas may be generated by decomposition of the products of inflammation within this cavity, but examples must be exceedingly rare.

The presence of air and liquid gives rise to splashing and sometimes metallic sounds, with the movements of the heart, which are heard on auscultation; and percussion over the præcordia elicits a tympanitic resonance. These cases belong among the curiosities of clinical experience. The treatment of pneumo-pericarditis involves the same principles as the treatment of pericarditis without the presence of air or gas.

CHAPTER II.

Endocarditis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Myocarditis.

INFLAMMATION of the membrane lining the cavities of the heart, or the endocardium, is called *endocarditis*. Our knowledge of the existence of this disease is one of the developments of modern pathological research. It is a highly important disease considered more especially in its relation to structural lesions of the valves and orifices of the heart.

The inflammation is doubtless in some cases acute, and in other cases subacute or chronic, but, as the symptoms and signs do not enable us to determine clinically the grade of inflammatory action, a division of the disease into the acute and chronic form is unnecessary.

Anatomical Characters.—The disease very rarely proves fatal during its progress, and, therefore, the opportunity of observing the morbid appearances is seldom offered. On this account the observations of Dr. Richardson in cases of endocarditis produced, artificially, in inferior animals, by the introduction into the blood of lactic acid, injected into the peritoneal cavity, are valuable.[1] These observations show arborescent redness from congestion of the vessels beneath the membrane, and considerable swelling of the valves, especially the auricular valves, from the exudation, beneath the membrane, of lymph with serum. More or less exudation also takes place on the free surface of the membrane covering the valves and tendinous cords. Much of this exudation must be washed away with currents of blood; that which remains sometimes assumes the form of patches of false membrane, but it is oftener disposed in the form of small masses, or beads, situated especially at the base or near the extremities of the valvular curtains and segments. These small masses are often observed, in greater or less number, varying in size from that of a pin's head to a millet-seed, oftenest in the auricular aspect of the mitral curtains, and the ventricular aspect of the aortic segments. According to Virchow they are due not to fibrinous exudation, but to morbid growth or proliferation of the connective tissue of the endocardium. Roughening the surface of the membrane, they become the nuclei of the so-called warty excrescences or vegetations, their size being increased by the deposit of fibrin from the blood within the cavities of the heart. In this way they may attain to a considerable size. It is not uncommon to find, attached to the valves, vegetations as large as a pea, a bean, a filbert, and even still larger. They may be loosely attached to the endocardium, so that but little force is required to detach them, or they may adhere with considerable firmness. They are liable to be separated during life, giving rise to *emboli*, to which reference has already been made, and which will be again referred to in other connections.

Aside from these products of inflammation, the membrane in certain situations, especially over the valves, loses its smooth, polished appearance, becoming rough and velvety. It is more easily separated than in

[1] *Vide* Prize Essay on Coagulation of the Blood, by W. B. Richardson, M. D.

health, owing to brittleness of the areolar tissue beneath it. Perforation of the valves, laceration and morbid adhesions of the valvular curtains or segments, are occasionally incident to the progress of endocarditis. These and other changes, however, are oftener remote than immediate effects of inflammation, and they will be considered under the head of valvular lesions, in another chapter. Ulcerations of the membrane characterize a small proportion of cases; the effects of so-called ulcerative endocarditis will be noticed in connection with the prognosis. In examinations of the heart after death, redness of the endocardial membrane and of the lining membrane of the vessels near the heart, is frequently found, which is due to staining with hematine dissolved out of the red corpuscles, and occurs after death. This appearance is no evidence of disease of the endocardium.

The anatomical characters of endocarditis are generally limited to the left side of the heart, that is, the left ventricle and auricle. The right cavities are very rarely the seat of endocardial inflammation, and never without inflammation of the left cavities. This statement, of course, applies to the disease as occurring after birth. There is reason to believe that endocarditis may occur during fœtal life, and that the reverse of the statement just made then takes place, viz., the right cavities, and not the left, are the seat of the inflammation. The inflammation is either limited to, or is especially marked in, the valvular portions of the endocardial membrane. This is probably owing partly to the presence of fibrinous tissue beneath the endocardium in these situations, and in part to the strain which falls upon the valves in the performance of their functions.

Clinical History.—Authenticated cases of endocarditis disconnected from other diseases which serve to mask its symptoms to a greater or less extent are wanting. The clinical history of the disease, therefore, so far as it is at present known, will require but a brief space. Our knowledge of the disease is confined chiefly to the cases in which it occurs in connection with acute articular rheumatism, and in a certain proportion of these cases it is associated with pericarditis. Pain referable to the præcordia is not a constant, and is rarely a prominent symptom. The pain, when present, is dull, not sharp or lancinating like the pain in pericarditis or pleuritis. The patient may complain of an obscure sense of distress in the præcordia, not amounting to pain. The action of the heart is morbidly excited. The organ beats with abnormal quickness and frequency, and its action may be irregular. The action of the heart may be found to be out of proportion to the force of the pulse. The local symptoms, in short, as regards the action of the heart, are those of palpitation. In proportion to the acuteness of the inflammation, doubtless febrile movement is induced, together with the symptoms of constitutional disturbance which accompany fever symptomatic of inflammation in other situations. The local and general symptoms, however, are often not prominent, and, so far as these are concerned, the disease is not infrequently latent. Hence the existence of the disease was unknown prior to the early part of the present century.

Pathological Character.—The morbid changes which belong to endocarditis are, in many respects, the same as in serous inflammations. But the inflammatory products in this situation are not retained to be removed by absorption, but are, in a great measure, carried by the currents of blood directly into the circulation.

It may be doubted whether suppuration often takes place upon the endo-

cardial surface. Newly-formed tissue, giving rise to morbid growths, is a result of inflammation in this situation. The warty vegetations which have been referred to are sometimes in part organized. Adhesion of parts in contact, viz., of the mitral curtains to each other, and the aortic segments to the walls of the aorta, is an occasional result of inflammation. It is stated by Bouillaud that the valves may become gangrenous as a result of inflammation; this must be exceedingly rare. As already stated, ulcerations sometimes occur, characterizing a form of the disease which is called ulcerative endocarditis.

Causation.—Endocarditis, in the great majority of cases, is not a primary disease. There is reason, however, to believe that it occurs as an idiopathic affection not very infrequently, and is overlooked in consequence of its latency as regards cardiac symptoms. This may be inferred from the number of cases in which valvular lesions referable to inflammation are found in persons who have never experienced the disease in the course of which endocarditis is apt to be developed, viz., articular rheumatism. As met with in practice, it is generally incidental to the disease just named. The proportion of cases of rheumatism in which it occurs is not settled. The statistics of different observers show a variation from two-thirds to nine per cent. A reason for this variation is that the existence of the disease has been often assumed on insufficient evidence. The ground for this statement will appear in connection with the consideration of the diagnosis. It is not to be doubted that the disease is frequently developed in the course of rheumatism. Endocarditis, like pericarditis, may perhaps in some cases precede the affection of the joints. It may occur at any time in the course of a rheumatic attack, but it is usually developed in the early or middle period.

When developed in the course of rheumatism, it is not from the transference of the affection of the joints to the endocardial membrane; that is, not by a metastasis, but, like pericarditis developed in the same connection, it is produced by the internal causative condition which gives rise to the articular affection. That this causative condition consists of a morbid material in the blood is probable, and the fact of the endocarditis being generally limited to the left side of the heart would seem to render it probable that the morbific agent is generated within the blood during its passage through the pulmonary organs. If the agent in the blood exerted its effect upon the endocardium by means of the vessels distributed to the heart, there is no apparent reason why the right side should not be affected as well as the left; but, assuming that the agent in the blood acts by being brought into direct contact with the endocardium, it is intelligible that this agent existing in the blood received into the left cavities from the pulmonary circuit should act upon the membrane lining these cavities, and that it should be eliminated, neutralized, or decomposed before the blood has passed through the systemic circuit, and reached the right cavities of the heart. This is the view taken by Richardson, and it is sustained by the fact that in his experiments of injecting lactic acid into the peritoneal cavity, endocarditis was produced not in the left, but in the right cavities of the heart, the acid being destroyed in these experiments before the blood passes through the pulmonary circuit and reaches the left cavities. Moreover, these experiments render it probable that the morbific agent which gives rise to the affections of the heart and joints in rheumatism is lactic acid produced in the blood during its passage through the lungs.

Endocarditis and pericarditis are not infrequently associated in cases

of rheumatism, and this compound affection is denominated *endo-pericarditis*. Rheumatic pericarditis very rarely, if ever, exists without endocarditis. The reverse of this, however, does not hold good; endocarditis is not infrequently developed without pericarditis.

Endocarditis, either with or without pericarditis, is developed, in a certain proportion of cases, in the course of Bright's disease. It is stated, also, to occur occasionally in the eruptive and continued fevers, and in cases of pyæmia. It may possibly be produced by contusions of the chest. It may be associated with pleuritis or pneumonitis, when it occurs in rheumatism or in other pathological connections. The most rational view in these cases is to attribute the coexisting affections to a common causative condition.

Diagnosis.—The symptoms in cases of endocarditis are insufficient for a positive diagnosis. The symptoms are even less diagnostic than those which belong to the clinical history of pericarditis, and the disease is oftener latent. The diagnosis of this disease, as well as of pericarditis, must rest on physical evidence. The exudation of lymph, or the deposit of fibrin upon the endocardium, gives rise to an endocardial murmur, and the diagnosis is to be based on the development of this murmur, taken in connection with the symptoms. The murmur is due to the roughening of the endocardial surface, and, as the anatomical changes are especially situated upon the curtains of the mitral valve, at least in cases of rheumatic endocarditis, the murmur is usually of mitral origin. The murmur is of a soft or bellows character. It accompanies the first sound of the heart; this is, it is systolic. It is heard loudest at or near the apex of the heart, and may be limited to this situation. As a rule, if, prior to the endocarditis, the patient were free from valvular lesions, the systolic murmur is not propagated far without the left border of the heart. It is probable that the anatomical changes which generally occur during the progress of the endocarditis rarely involve immediate valvular insufficiency, either at the mitral or aortic orifice. Hence, the mitral murmur may not proceed from an actual regurgitant current from the ventricle to the auricle. It is not, then, strictly correct to call it a mitral regurgitant murmur. It is an intra-ventricular murmur, or it may be called a *mitral systolic murmur*, this term not implying the occurrence of regurgitation.

The physical evidence of endocarditis is not afforded by the existence of the murmur just named. A mitral murmur exists sufficiently often without denoting existing inflammation. It may proceed from valvular lesions which are to be presently considered. To be evidence of endocarditis, the murmur must be developed under observation; in other words, the practitioner must be satisfied that the murmur which he discovers did not exist on a previous examination. As it is generally in cases of rheumatism that endocarditis occurs, let it be assumed that, on the first examination of a patient affected with rheumatism, a mitral murmur is found. The murmur is not proof of endocarditis, for it is not known that the murmur did not exist prior to the rheumatic attack. The existence of endocarditis is only probable, and the probability of the disease is greater if this be the first attack of rheumatism. But if, on a first examination, no murmur be found, and subsequently, a mitral murmur become developed, it is evidence of endocarditis. The evidence is strengthened, if, at the same time, pain or præcordial distress and excited action of the heart point to the occurrence of a cardiac complication.

Reference has been made, thus far, to a mitral murmur only as evidence of endocarditis. The exudation of lymph, and the deposit of fibrin at the

aortic orifice, may occur in this disease, giving rise to an aortic murmur. I have been led, however, to think that an aortic and a pulmonic murmur are not infrequently developed in cases of rheumatism without endocarditis, more especially in females, being due to the condition of the blood; in other words, being inorganic murmurs. Hence, I would not base a positive diagnosis of endocarditis on the development of an aortic murmur alone, unless the symptoms, at the same time, denoted a cardiac complication, and pericarditis did not exist. Irrespective of cases of rheumatism, it is well known that an aortic murmur with the first sound *i. e.*, systolic, is sufficiently common as an inorganic murmur, and, alone, is never proof of endocarditis. It may be doubted if insufficiency of the aortic valve be ever an immediate result of endocarditis; at all events, I have never met with an aortic regurgitant murmur developed in the progress of endocarditis.

In view of the fact that in the great majority of the cases of endocarditis it is a complication of articular rheumatism, not only do we seek for the evidence of its development in the course of the latter disease, but the existence of articular rheumatism renders the diagnosis more complete than if this disease did not exist.

An endocardial murmur produced by endocarditis is generally permanent, but I have repeatedly known it to disappear after recovery from rheumatism. I have known an aortic and a mitral murmur to continue for several years after recovery and at length to disappear entirely. In cases of endo-pericarditis, the endocardial exists with an exocardial or friction murmur. In general, the two murmurs may be readily distinguished, and each referred to its source.

Prognosis.—In the great majority of cases, endocarditis involves no immediate danger. The danger is, for the most part, remote, relating to the valvular lesions which are apt to follow. (*Vide* Chapter III.) The persistence of inflammation in a chronic form is not determinable. The continuance of endocardial murmur is not proof that inflammation persists; roughening of the membrane from vegetations or lymph which remains will suffice to produce murmur. The chief source of important morbid effects and of danger, exclusive of valvular lesions, is embolism. Vegetations, or masses of fibrin of greater or less size, are liable to be detached, and, forming emboli, occasion obstruction (infarction) of arteries in different organs. Passing, of course, into the systemic circulation, they are especially apt to become lodged in the spleen, where they give rise to characteristic lesions. (*Vide* page 78.) Occasionally they give rise to analogous lesions in the kidneys, and sometimes, although very rarely, the emboli are carried to the liver. The affection hereafter to be considered under the name acute or yellow atrophy of the liver, is supposed to be an effect of embolism of the hepatic artery. Again, cerebral embolism may occur, and cases have occurred in which gangrene of the lower limbs has resulted from embolic obstruction of their distributing arteries. Moreover, the washing away of lymph or fibrin in small particles may occasion capillary embolism. For a general account of embolism, the reader is referred to the first part of this work. (*Vide* page 71, *et seq.*) These are accidents incidental to endocarditis in some cases. In general, as occurring in the pathological connection in which it usually occurs, viz., in the course of acute articular rheumatism, and disconnected from pericarditis, endocarditis involves no immediate danger, gives rise to no symptoms denoting gravity of disease, is frequently completely latent, and is an important complication chiefly because it may be the foundation for valvular lesions

which, after the lapse of many months, or it may be many years, occasion serious consequences.

The so-called ulcerative endocarditis is characterized by small ulcerations limited, in the majority of cases, to the valves, but sometimes occurring in portions of the endocardium which are in contact with the muscular walls of the heart. These ulcerations may lead to perforation of the valves, and, also, to aneurismal dilatations. The immediate pathological effects, however, which belong to certain cases of ulcerative endocarditis, relate to embolism and an infection of the blood. The decomposed tissue and morbid products which are thrown off in the formation of the ulcers, and from the ulcerated surfaces, although the quantity is small, may be sufficient to infect the blood. The solid particles in the detritus, at the situations where they become lodged, not only cause mechanical obstruction, or infarctus, but they excite suppurative inflammation, and, perhaps, gangrene; and these may prove foci whence a further infection of the blood is produced. In short, septicæmia and pyæmia are sometimes attributable, thus, to ulcerative endocarditis; and, bearing this fact in mind, the existence of these blood-conditions, without other obvious causation, should lead us to examine for the signs of endocardial disease. Among the systemic arteries which are liable to receive the detritus in cases of ulcerative endocarditis, are the mesenteric; and embolism here leading to intestinal ulcerations, the cases may simulate closely typhoid fever. Happily, pyæmic and septic conditions attributable to endocarditis are extremely rare. In ulcerative endocarditis the ulcerations are generally limited to the left side of the heart. Exceptionally they occur in the right side, and the local embolic effects then, of course, take place in the lungs.[1] The prognosis in cases of embolism, pyæmia, and septicæmia attributable to ulcerative endocarditis, is the same as when these conditions occur in other pathological connections. From the two last named conditions recovery is to be expected in only a small proportion of cases.

Treatment.—The inflammation in endocarditis being confined, generally, to one side of the heart, and limited chiefly to the valvular portion of the endocardium, does not occasion great constitutional disturbance. Following the general principles which are to govern the employment of bloodletting, it is never called for. Depletion by means of saline purgatives or laxatives may be advisable.

Præcordial pain and disturbed action of the heart indicate anodyne remedies and soothing applications to the chest. Blisters, with reference to these symptoms, are of doubtful propriety. Sinapisms and stimulating liniments will secure all the advantages to be derived from counter-irritation.

Measures addressed to the supposed causative condition of the blood are rationally indicated. Occurring generally in connection with rheumatism, if the local affections, this of course included, depend on the presence of a morbid material in the blood, it is plainly an object either to neutralize or eliminate this material. The means to be employed for this object will be hereafter considered in connection with the subject of rheumatism.

The remote evil consequences of endocarditis proceed from the thickening, morbid growths and the deposit of fibrin upon the valvular portion of the endocardium. It is, therefore, undoubtedly desirable to limit and remove these immediate effects of the inflammation. The fibrin of the

[1] *Vide* "Case of Ulcerative Endocarditis of Right Heart with Sloughing of Lungs, etc., by W. Moxon," Trans. Path. Soc., of London, 1871, p. 107.

blood is increased in acute rheumatism more than in any other disease, and for this reason, perhaps, fibrinous deposits are apt to take place. With this view, measures to reduce the excess of fibrin, and to favor its liquid state, are rationally indicated. Alkaline remedies and ammonia, there is reason to believe, contribute to the latter of these two ends. Mercury has been supposed to diminish the amount of fibrin in the blood. That it possesses this power, however, has been inferred rather than demonstrated, and the correctness of the inference admits of doubt. It may be doubted whether the fibrin deposited upon the membrane is ever absorbed; it either remains or is washed away, gradually or in mass, by the current of blood.

The treatment in the cases in which ulcerative endocarditis exists and causes the effects noticed in connection with the prognosis, is not embraced in the foregoing remarks. The indications, however, in these cases are those which relate to embolism in different situations, and to pyæmia and septicæmia. These indications need not be here considered.

The practitioner should bear in mind that the persistence of an endocardial murmur is not sufficient ground for sorbefacient or other remedies. The persistence of the murmur is not evidence that the inflammation continues. The treatment of endocarditis should cease when the local and general symptoms of the disease are no longer present.

Myocarditis.

Inflammation of the muscular structure of the heart is rare. When it occurs it is generally in connection with endocarditis or pericarditis, singly or combined. It may occur, however, irrespective of either of these affections. Suppuration may take place as a result of myocarditis, the pus being either collected in abscesses or infiltrated. The pus may be discharged into the pericardial sac, giving rise to pericarditis, or into one of the cavities of the heart, causing purulent infection of the blood. Rupture of the heart may be a consequence of inflammation and suppuration. An abscess in the inter-ventricular septum may lead to perforation. Induration or sclerosis is a result of interstitial inflammation. Aneurismal dilatation is still another. The inflammation is oftener seated in the walls of the left, than of the right, ventricle. Perhaps the most frequent of the causes, exclusive of endocarditis and pericarditis, is embolism of a branch of the coronary artery. It may sometimes be imputed to syphilis. It is a serious affection, as impairing, in proportion to its extent, the muscular power of the heart, and as involving a liability to the accidents just stated. Associated with either endocarditis or pericarditis, or both, it adds, of course, to the gravity and danger. Its coexistence with these affections, and its existence without them, cannot be determined during life.

CHAPTER III.

VALVULAR LESIONS WITH ENLARGEMENT OF THE HEART.

Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment.

HAVING considered, in the two preceding chapters, the inflammatory affections of the heart, the structural lesions of this organ next claim attention. The structural lesions relate, in the first place, to the valves and orifices of the heart. These are known commonly as *valvular lesions*. Other lesions relate to the walls and cavities of the heart. Enlargement of the heart, in the great majority of cases, proceeds from valvular lesions, and the latter, sooner or later, in the great majority of cases, give rise to cardiac enlargement. In considering, therefore, valvular lesions, I shall also consider enlargement as dependent thereon, and afterward notice enlargement occurring without valvular lesions.

Anatomical Characters.—Valvular lesions are situated, in the great majority of cases, in the left side of the heart, that is, at the mitral and the aortic orifice. Tricuspid and pulmonic lesions are comparatively rare. The morbid appearances in different cases are extremely diversified. The valvular curtains and segments are frequently thickened and contracted; or, they may be simply encumbered with vegetations of greater or less size, without being incapacitated for the performance of their function. They are sometimes rendered more or less rigid by calcareous deposit. The mitral curtains are not infrequently united at their sides so as to form a funnel-shaped canal leading from the auricle to the ventricle, the opening consisting of a small slit, called the button-hole contraction of the mitral orifice. The aortic segments, expanded and rigid, in some cases diminish the size of this orifice to that of a crow's quill, or even much smaller. The valves may become atrophied, and are liable to rupture or perforations. Rupture of one of the valves is an occasional accident without prior disease, when an excessive strain is induced by the violent action of the heart in severe muscular exertions; under these circumstances the tendinous cords which unite the extremities of the mitral curtains to the papillary muscles are especially apt to give way. For a full description of the varied changes which are observed in different cases of valvular lesions, the reader is referred to works on morbid anatomy.

In a clinical point of view, all the diverse alterations of structure embraced under the name valvular lesions may be arranged, according to their effects upon the circulation, into the following groups: *First*, obstructive lesions, that is, lesions which impede the flow of blood by producing contraction of the orifices; *second*, regurgitant lesions, that is, lesions which interfere with the function of the valves, rendering them incompetent or insufficient, and consequently allowing backward or regurgitant currents; *third*, lesions which involve both obstruction and regurgitation; and, *fourth*, lesions which involve neither obstruction nor regurgitation, but give rise to morbid sounds by roughening the surface over which the blood flows. The lesions belonging to the last group are of

little or no immediate importance, and, although giving rise to abnormal sounds known as endocardial or bellows murmurs, they may be quite innocuous.

The lesions which involve either obstruction or regurgitation, or both, lead to enlargement of the heart. They produce this result by giving rise to over-repletion of certain of the cavities of the organ. Limiting attention to the lesions situated at the mitral and aortic orifice, the primary effect differs according to the situation. Mitral obstructive and regurgitant lesions, as a rule, produce, first, dilatation of the left auricle, because these lesions give rise, as the primary effect, to over-repletion of this cavity. Dilatation of the left auricle occasions pulmonary obstruction, because this cavity, being already distended, does not offer space for the free admission of the blood returned to the heart from the lungs. As a consequence of pulmonary obstruction, blood accumulates in the right ventricle, and hence occurs enlargement of this portion of the heart as the next effect. Over-repletion of the right auricle is the next effect, leading to dilatation of this cavity; and finally, as a consequence of obstruction of the systemic venous system due to the right auricle being constantly filled, the left ventricle may become enlarged. This is the series of effects caused by mitral lesions which involve either obstruction or regurgitation, or both.

Lesions of the aortic orifice, either obstructive or regurgitant, or both, produce a similar series of effects with a different point of departure. The over-accumulation is first in the left ventricle, and this becomes enlarged. Dilatation of the left auricle follows, and successively the right ventricle and right auricle are enlarged, if life be sufficiently prolonged. Cases are not infrequent in which obstructive or regurgitant lesions are situated at both the mitral and aortic orifice. The effects of aortic and mitral lesions are combined in these cases.

Enlargement of the heart, with or without valvular lesions, is of two kinds, viz., *first*, enlargement due to abnormal growth or hypertrophy, and, *second*, enlargement due to dilatation. In examinations after death from valvular lesions with enlargement, the enlargement is not in general found to be exclusively by either hypertrophy or dilatation, but the two kinds of enlargement are combined. A marked difference exists in different cases, as regards the symptoms, signs, and the danger, according to the predominance of either hypertrophy or dilatation. As a rule, hypertrophy of the ventricles takes place before dilatation. The over-repletion of the ventricular cavities induces augmented power of muscular action, and this causes hyper-nutrition or abnormal growth. The ventricles grow in consequence of long-continued increased power of muscular action, precisely as the voluntary muscles become enlarged as a consequence of exercise.

The hypertrophic growth of the ventricles has its limit, as the enlargement of voluntary muscles is limited. The voluntary muscles cannot increase indefinitely, but, after a certain amount of increased growth, it ceases, notwithstanding the exercise of the muscle is continued. So with the heart—the hypertrophy at length reaches a point beyond which no further growth takes place. The extent to which the heart can increase by hypertrophy varies in different persons, as the point at which the increase of the voluntary muscles varies. The enlargement by hypertrophy is represented by the increased weight of the heart. In cases in which a very great amount of hypertrophy takes place, the weight of the heart is found to be four or five times greater than in health.

Dilatation, sooner or later, follows hypertrophy. When nutrition can

no longer be excited to cause progressive growth, the continued over-repletion of the cavities causes the walls to yield and dilatation takes place. The dilatation goes on, and at length it predominates over the hypertrophy; that is, in relative amount the former exceeds the latter. The enlargement by hypertrophy is due to a vital process, viz., hyper-nutrition; but the enlargement by dilatation is produced mechanically. Hypertrophy involves augmented power of the muscular walls; dilatation involves diminished power, or weakness, in proportion as the cavities are enlarged. In proportion as dilatation predominates over hypertrophy, the volume of the heart, rather than its weight, is increased.

Enlargement may be much more marked in one portion of the heart than in another portion, or it may be limited to a part of the organ. The right ventricle, for example, may be chiefly or exclusively the seat of enlargement in connection with mitral valvular lesions, and this may hold true of the left ventricle in connection with aortic valvular lesions. The left ventricle may be enlarged by predominant dilatation while the right ventricle is enlarged by predominant hypertrophy, and *vice versâ*.

Clinical History.—Valvular lesions, so long as they involve neither obstruction nor regurgitation, give rise to no symptoms of disease, and their existence is only ascertained by means of physical signs. Lesions involving obstruction or regurgitation, or both, as a rule, do not occasion much inconvenience until they have led to enlargement of the heart. Moreover, as a rule, lesions occasion suffering, and are attended with danger, in proportion to the enlargement which they have produced, and chiefly to the enlargement due to dilatation.

The first symptoms proceeding from mitral obstructive or regurgitant lesions pertain to the respiratory system. Deficiency of breath on exercise is, for some time, the chief inconvenience. This progressively increases, in proportion as the obstruction to the pulmonary circulation increases. The patient is at length obliged to discontinue any active muscular exertion, but may be comfortable while remaining quiet. Dyspnœa finally becomes habitual, and is more or less prominent as a symptom after dilatation of the right ventricle has taken place. A still further development of this symptom renders the patient unable to lie down, constituting, then, orthopnœa. This may be due, in a measure, to coexisting pulmonary accidents. Cough and more or less muco-serous expectoration are incidental to congestion or a low grade of inflammation of the bronchial mucous membrane. An abundant serous expectoration sometimes occurs, constituting bronchorrhœa. Hæmoptysis is not infrequent, the hemorrhage being usually small. This event generally denotes simply bronchorrhagia, but occasionally blood is extravasated into the air-cells, constituting what is commonly called pulmonary apoplexy. Pulmonary œdema is another intercurrent event which is liable to occur, increasing the suffering from dyspnœa. Hydrothorax is still another source of embarrassment of respiration. "Pigment induration" of the lungs dependent on persistent congestion, caused by regurgitant and obstructive mitral lesions, has been noticed in a preceding chapter (*vide* page 196). This enters into the rationale of dyspnœa in some cases.

After enlargement of the heart takes place, its action, so long as the hypertrophy predominates, is abnormally strong. This may be perceived by the hand placed over the præcordia. The patient, however, rarely complains much of palpitation, having become accustomed to the gradual increase of the power of the heart's action. The pulse is small and weak in proportion to the amount of obstruction or regurgitation,

each of these immediate effects of the lesions lessening the quantity of blood propelled into the aorta and its branches by the systole of the left ventricle. The quantity of blood contained in this ventricle at the time of the systole may sometimes be so much lessened that the radial pulse is lost; hence one source of intermission of the pulse; another source is an actual intermission of the ventricular systole. Inequality of the successive beats of the pulse, as regards volume and force, represents unequal supplies of blood from the left auricle to the left ventricle. Irregularity in the action of the heart is not infrequent. Intermittency of the pulse and inequality of successive beats, due to deficiency of the supply of blood to the left ventricle, are characters which denote mitral contraction rather than regurgitation.

The characters pertaining to the form of the pulse, as ascertained by the sphygmograph, are notable variations, in different pulsations, in the length of the line of ascent, shortness of this line in a greater or less number of pulsations, its vertical direction, and marked dicrotism in the line of descent. In cases of mitral obstruction, according to Marey's observations, the line of ascent is longer and the variations in different pulsations are less, the direction of this line being also vertical, and the line of descent showing dicrotism. These characters denote quickness of the ventricular systole, feeble arterial tension, and want of uniformity as regards the quantity of blood sent into the aorta in different beats.

Pain is rarely a prominent symptom during the progress of mitral lesions, but uneasiness and an indefinite sense of distress, referred to the præcordia, may be complained of. Nor are there any notable symptoms referable to the nervous system. There is a marked contrast, as regards mental anxiety and apprehension, between the cases in which the action of the heart is disturbed by lesions and those in which the disturbance is purely functional. In the former, mental depression is proportionate to the physical suffering, and patients are apt to be apathetic with respect to danger; in the latter, the mind is depressed out of proportion to the actual ailment, and patients are harassed by imaginary fears. If dyspnœa be a prominent symptom, the loss of sleep adds to the sufferings of the patient. The sleep which is obtained is apt to be imperfect and disturbed by frightful dreams. It is not uncommon for patients to be unable to lie down for many weeks before death, short periods of sleep being obtained by inclining the body forward and resting the elbows on the knees or on some solid support.

Sooner or later, if life be not cut off by some intercurrent affection, dropsical effusion takes place into the areolar tissue and serous cavities. The lower limbs generally first become œdematous, afterward the face and body, and more or less liquid accumulates within the peritoneal and pleural sac. The limbs and body sometimes become greatly swollen, and the scrotum acquires an enormous size. The skin on the lower limbs, under these circumstances, may become erythematous; ulcerations or fissures are apt to occur, with abundant draining away of serum. The face is congested, and not infrequently the lips are livid. The dusky hue, due to congestion or cyanosis, combined with œdema, gives to the face an appearance which contrasts with the pallid aspect characterizing general dropsy from renal disease. General dropsy arising from mitral lesions occurs after enlargement by dilatation of the right side of the heart has taken place, and is dependent mainly on the venous obstruction which the latter condition involves. Tricuspid regurgitation, which exists to some extent normally, is increased in this condition, and adds to the venous obstruction. This condition of the right cavities gives rise to turgescence

of the cervical veins, especially when the patient is sitting or standing, and this turgescence is sometimes very great. Under these circumstances, pulsation of the superficial veins of the neck, occurring synchronously with the auricular or ventricular systole, or with both, is not uncommon. Jugular pulsation is, however, observed in some cases without venous turgescence, and when dropsy has not taken place. Other circumstances than dilatation of the right side of the heart may contribute to the occurrence of dropsy, for example, anæmia.

The organs composing the digestive system suffer from the congestion arising from dilatation of the right side of the heart. The appetite and digestion become impaired; enlargement of the liver is sometimes observed. Prior to the occurrence of dilatation, however, the appetite and digestion may be but little impaired. Nutrition may be but little affected even after the lesions have led to considerable suffering. Emaciation is not an early, nor, at any time, a marked effect of valvular lesions of the heart. The kidneys participate in the congestion, and the secretion of urine is apt to be scanty. Albumen in small quantity may be present in the urine, as an effect of renal congestion, without denoting degenerative disease of the kidneys. Hemorrhage from the stomach or intestines is an occasional effect of the congestion of the mucous membrane in these situations. Hemorrhoids and epistaxis belong in the same category.

Aortic lesions involving obstruction or regurgitation usually give rise, as the first symptom, to inconvenience from the increased power of the heart's action, the primary effect of these lesions being hypertrophy of the left ventricle. The patient complains of palpitation, especially on exercise or under the influence of mental emotions. The action of the heart is felt, by the hand over the præcordia, to be inordinately strong, and the dress or portions of the body may present visible movements with each ventricular systole. Pain is more apt to be present than in cases of mitral lesions, and, irrespective of the painful affection called *angina pectoris*, is not infrequently a prominent symptom. Cough, expectoration, dyspnœa, and hæmoptysis, dependent on pulmonary congestion, and the accidents incident thereto, occur less frequently in connection with aortic than with mitral lesions. Pulmonary congestion, dependent on dilatation of the left auricle, does not occur until the left ventricle becomes sufficiently dilated to render the mitral valve insufficient, and the disease may end fatally without this result taking place.

If the lesions produce contraction, with but little or no regurgitation, the pulse is simply weakened, but not in a notable degree, even when the contraction is considerable. Under these circumstances, however, the pulse is frequently weak in proportion to the power of the heart's action; the force of the stroke felt by the finger over the artery is in striking contrast to the impulse felt by the hand over the præcordia. If the lesions impair the aortic valve so as to involve considerable regurgitation, the pulse is somewhat distinctive of this fact. The artery strikes against the finger with quickness, and appears instantly to recede; the stroke is not sustained, and the pulse is said to be *jerking* or *collapsing*, giving a sensation as if a "ball of blood were shot through the artery." This is due to the fact that, directly after the ventricular systole, the aorta is emptied by the regurgitant current, and this current and the direct current come into collision when the ventricle contracts. Another symptom pertaining to the arteries, in some cases, is distinctive of free aortic regurgitation, viz., visible movements of the arterial trunks which are superficially situated, such as the carotid, temporal, subclavian, brachial, etc. The appearance caused by the movements of these vessels is some-

times very striking, and is so distinctive that aortic regurgitation is rendered highly probable by this symptom alone.

The tracings by the sphygmograph in cases of aortic obstructive lesions give an oblique and curved line of ascent, denoting the slowness with which the blood is driven into the aorta; and in the line of descent, dicrotism is either slight or wanting. In cases of aortic regurgitation, the line of ascent is vertical, and dicrotism in the line of descent is marked. If, as is not infrequent, senile induration of the arteries coexist, the summit presents a plane of greater or less length; if this condition of the arteries do not exist, the upper part of the diagram representing a pulsation is pointed, and the line of ascent may be notched near its upper extremity.

General dropsy occurs in only a small proportion of cases of aortic lesions, that is, dropsy arising from the cardiac affection. This is owing to the fact that life is generally destroyed before the lesions have led to dilatation of the right cavities of the heart. Hence, turgescence of the cervical veins and jugular pulsation do not belong to the clinical history of aortic lesions. This statement also holds good with respect to congestion of the abdominal viscera and the kidneys.

Aortic regurgitant lesions are apt to give rise to symptoms proceeding from a sudden increase of the accumulation of blood within the left ventricle sufficiently to embarrass the action of this ventricle by distention. This ventricle becoming overloaded by the regurgitant current in addition to the direct mitral current, the ventricular walls are distended so as to weaken their power of contraction. This is a rational explanation of paroxysms of distress to which these lesions give rise. The action of the heart is irregular and spasmodic, and the patient experiences a sense of great oppression at the præcordia, with a feeling of impending death. These attacks are excited, at first, by muscular exercise or mental emotions, but, after a time, they may occur without any obvious exciting cause. They occasion great distress, and sudden death may take place in an attack of unusual violence, the left ventricle being paralyzed by over-distension. They are more frequent and serious when dilatation of the left ventricle predominates over hypertrophy, yet they may be more or less frequent and violent, and may prove fatal, while hypertrophy is predominant. The occurrence of these attacks renders patients affected with aortic lesions more anxious and apprehensive than those affected with mitral lesions. As conducive to these paroxysms and the liability to sudden death, more or less importance belongs to defective circulation through the coronary arteries, which is incident to free aortic regurgitation. This defective circulation arises from the fact, as explained by Mauriac,[1] that the blood is forced into these arteries, not by the ventricular systole, but by the recoil of the aorta after the systole. In order that this recoil force shall affect the circulation in the coronary arteries, the aortic valves must be sufficient; if these valves be insufficient, the recoil force is expended on the aortic regurgitant current, and the heart suffers from a defective supply of blood. The weakness of the ventricles from this cause, and, also, from venous congestion, due to the fact that, when the heart contracts feebly, the blood within the veins of the ventricles is imperfectly expelled, conduces to paralysis, from over-distension, of the left ventricle.

Aortic and mitral lesions, involving either obstruction or regurgitation, or both, in each situation, are not infrequently associated in the same case. Certain of the symptomatic phenomena arising from lesions at the

[1] Nouveau Dictionnaire, Paris, 1868, Art. Cœur.

mitral and aortic orifice are then combined. Mitral obstruction and regurgitation, however afford protection against the paroxysms of distress and the liability to sudden death incident to aortic regurgitation, by preventing over-distension and paralysis of the left ventricle. In this point of view, the former are compensatory, or conservative.

Tricuspid and pulmonic lesions, as already stated, are comparatively rare. In the majority of the cases in which they exist, they are congenital. They are, therefore, most liable to be met with in young subjects. Tricuspid lesions, in proportion as they involve obstruction or regurgitation, lead, primarily, to dilatation of the right auricle, and thence to systemic congestion. General dropsy, under these circumstances, is likely to occur early, without having been preceded by the symptoms denoting pulmonary congestion. Turgescence of the cervical veins and venous pulsation are also early symptoms in such cases. Lesions at the pulmonic orifice, involving contraction or regurgitation, in like manner, soon lead to dilatation of the right auricle and the symptomatic phenomena dependent thereon.

Pathological Character.—The primary evils of valvular lesions are mechanical. They do harm by obstructing the direct or normal currents of blood, and by allowing abnormal or regurgitant currents to take place. They induce hypertrophy or morbid growth of the walls of the heart, by increasing the force of the heart's action, and thereby inducing hypernutrition. This result, it is to be borne in mind, is not an evil. The hypertrophy resulting from valvular lesions is conservative. The augmented power of action which the heart acquires with its increased muscular growth enables it better to carry on the circulation despite the obstacles afforded by obstructive and regurgitant lesions. The hypertrophy is, to a certain extent, compensatory for the obstacles which these lesions afford. This fact has an important practical bearing on the management. Dilatation of the cavities is another result of valvular lesions. This result is an evil. The heart is weakened in proportion as it becomes dilated. The circulation then suffers, not only from the obstacles afforded by the valvular lesions, but from the diminished power of the heart's action. As a rule, it is not until dilatation predominates over the pre-existing hypertrophy, that distressing and grave symptoms of disease of the heart are developed; and the suffering and danger increase as the dilatation progresses.

It is important to bear in mind that valvular lesions do not involve existing inflammation. The atrophy and calcareous degeneration which lead to contraction of the valves, rigidity, rupture, etc., are not inflammatory processes, although they may be, and, in a large proportion of cases, probably are, the after-effects of inflammation.

Causation.—In the majority of cases, valvular lesions originate in the endocarditis which complicates acute articular rheumatism. Of sixty-one cases which I analyzed, some years ago, with reference to this point, rheumatism had existed at a former period of life in forty-three. And of these forty-three cases, mitral lesions alone existed in twenty, aortic lesions alone existed in seven, and mitral with aortic lesions existed in sixteen. The degenerative changes which follow endocarditis lead to obstruction or regurgitation after a period more or less remote. When the evils or inconvenience resulting from valvular lesions are sufficient to lead the patient to seek for medical aid, it may be found that one or more attacks of rheumatism were experienced five, ten, fifteen, or twenty years before.

And when cases first come under observation, more or less enlargement of the heart has already taken place. Enlargement, indeed, has probably existed for a long time, and it may not be until the heart becomes weakened by dilatation, that the patient applies to the physician. In some of the cases in which valvular lesions have not been preceded by rheumatism, their point of departure may have been in an endocarditis not rheumatic, for it is probable that non-rheumatic endocarditis occurs not very infrequently when its existence is overlooked. Lesions arise from the atheromatous and calcareous deposit and atrophy of the valves, leading to their perforation and rupture. Moreover, rupture of the valves or tendinous chords sometimes results from the violence of the heart's action, without any previous structural change. When valvular lesions have not originated in rheumatic endocarditis, there is reason to believe they are often due to syphilis. My colleague, Prof. Janeway, one of the Curators of Bellevue Hospital, has been led to this conclusion by finding that syphilis enters into the previous history of a large proportion of the cases in which valvular lesions occur in those who have never had rheumatism. This statement applies especially to cases of valvular lesions occurring prior to middle or advanced age.

Enlargement of the heart, as already stated, is an effect of the over-accumulation of blood in the cavities, in consequence of obstruction and regurgitation. And of the two forms of enlargement, hypertrophy and dilatation, the former precedes the latter.

Diagnosis.—The existence of valvular lesions can be determined with positiveness, only by means of auscultatory signs. By means of signs, the existence of lesions, their situation, and their character as regards being obstructive or regurgitant, may generally be ascertained. Lesions situated at the different valves and orifices are represented by endocardial murmurs, and the presence of these is evidence of the existence and situation of the lesions. It will suffice here to enumerate the several organic murmurs produced within the heart, together with the distinctive characters of each and its significance. They are naturally arranged into mitral, aortic, tricuspid, and pulmonic murmurs.

Mitral murmurs.—A murmur heard with the first sound of the heart, *i. e.*, systolic, having its maxmum of intensity at, or near, the situation of the apex-beat, or perhaps limited to that situation, represents mitral lesions. These lesions may or may not involve insufficiency of the valve and consequent regurgitation. If a regurgitant current exist, the murmur is properly called a *mitral regurgitant murmur*. But as a mere roughness of the valve may give rise to a murmur with the characters just mentioned, without regurgitation, the name just given is not always strictly correct. A better name is *mitral systolic murmur*, with or without regurgitation. If the murmur be diffused beyond the apex, around the left lateral surface of the chest, and heard on the back near the lower angle of the scapula on the left and sometimes on the right side, mitral regurgitation may be inferred. If the murmur be heard only around the apex and over the body of the heart, it does not afford proof of regurgitation; it is then, simply, a mitral systolic murmur. A mitral systolic murmur, regurgitant or non-regurgitant, is not transmitted above the heart, and is not heard over the carotid arteries. This murmur may be soft (bellows-like) or rough, and sometimes it is musical.

A murmur heard after the second, and just before the first sound of the heart, *i.e.*, presystolic, continuing up to the first sound and instantly arrested when this sound occurs, also represents, generally, mitral lesions.

This murmur is heard at and near the apex, and is usually confined within a circumscribed area around the apex. It is almost always rough, resembling a sound produced by throwing the lips or tongue into vibration with the expired breath. This murmur is produced especially by contraction of the mitral orifice in consequence of the union, at their sides, of the mitral curtains, forming a buttonhole-like slit. The murmur represents mitral contraction with occasional exceptions. In some cases in which free aortic regurgitation exists, the left ventricle becoming filled before the auricles contract, the mitral curtains are floated out, and the valve closed when the mitral current takes place, and, under these circumstances, this murmur may be produced by the current just named, although no mitral lesion exist.[1] This murmur is called the *mitral direct murmur*. Dr. Gairdner has proposed, as a better name, the *auricular systolic murmur*.

The two mitral murmurs not infrequently exist together; but either may exist without the other.

Aortic murmurs.—A murmur with the first sound, or a systolic murmur, heard with its maximum of intensity at or above the base of the heart, and generally propagated into the carotids, is called an *aortic direct murmur*. This murmur may represent aortic lesions, and it is then called organic, or it may be due to a morbid condition of the blood, without aortic lesions, and it is then called an inorganic or an anæmic murmur. The following circumstances render it probable that the murmur is inorganic or anæmic. The evident existence of anæmia; the absence of other signs of cardiac lesions; the variableness of the murmur, being sometimes present and sometimes wanting, and differing much at different times in intensity; the presence of murmur in the larger arteries, such as the carotid, subclavian, etc., and a continuous murmur in the veins of the neck commonly known as the venous hum. Attention to these points will generally suffice for determining whether an aortic direct murmur be organic or inorganic. The organic murmur denotes lesion of some kind, but not necessarily obstructive; that is, the lesion may simply render the membrane at or near the aortic orifice rough, without involving obstruction to the current. The murmur may be soft or rough, and it is sometimes musical.

An aortic murmur with the second sound of the heart, *i.e.*, diastolic, heard usually at the base, but, in most cases, having its maximum a little below the base, on or near the left margin of the sternum, is called an *aortic regurgitant murmur*. It represents insufficiency of the aortic valve and consequent regurgitation from the aorta into the left ventricle. This murmur may be more or less loud and prolonged; it is generally soft, but sometimes rough, and it may be musical.

The aortic direct and aortic regurgitant murmur not infrequently exist in combination, but either may be present without the other. One or both of the aortic murmurs coexist with either or both of the mitral murmurs in the cases in which mitral and aortic lesions are associated.

Tricuspid murmurs.—Tricuspid lesions are comparatively rare, and hence a murmur referable to this orifice is infrequent. A *tricuspid regurgitant murmur* occasionally exists, representing an unusual amount of regurgitation from the right ventricle to the right auricle, with, perhaps, hypertrophy of the ventricle. It occurs with the first sound, and is to be distinguished from a *mitral regurgitant murmur* by its being either

[1] *Vide* article on cardiac murmurs, by the Author, in the American Journal of the Medical Sciences, No. for July, 1862.

limited to, or having its maximum of intensity at, the right inferior border of the heart, viz., near the ensiform cartilage. It is apt, without care, to be confounded with a mitral regurgitant murmur. A tricuspid direct murmur is exceedingly rare, owing to the fact that lesions analogous to those which give rise to a mitral direct murmur, are so infrequent at the tricuspid orifice.

Pulmonic murmurs.—A *pulmonic direct murmur* is not of very infrequent occurrence. It is with the first sound of the heart, and is heard at, or above, the base, over the pulmonary artery, viz., in the second intercostal space near the left margin of the sternum. It is to be distinguished from an aortic direct murmur by its situation as just stated, coupled with its non-transmission into the carotids. It represents pulmonic lesions, when it is not inorganic or anæmic, as it not unfrequently is. The circumstances which render it probable that it is inorganic are the same as when the question is as to the organic or inorganic character of an aortic direct murmur.

By means of the foregoing murmurs, the diagnosis of valvular lesions is made, but it is important to bear in mind that neither the extent nor gravity of lesions is determinable by the murmurs. Whether the direct murmurs are produced by lesions which involve obstruction, or not, cannot be determined by the study of the murmurs alone; and whether the regurgitant murmurs proceed from much or little regurgitation, must be ascertained by other evidence than that which the murmurs afford. The intensity of the murmurs is no proof of the gravity of the lesions; slight or innocuous lesions may give rise to loud murmurs, and grave lesions may be represented by feeble murmurs. Nor does the character of the sound as regards softness, roughness, or a musical intonation, furnish any definite information respecting the extent or gravity of the lesions. With reference to this important point of investigation, therefore, evidence is to be sought for elsewhere. Symptoms relating to the circulation, which have been considered under the head of the clinical history, shed light upon this point, but, in addition, other physical signs are to be taken into account.

A comparison of the second sound of the heart as produced, separately, at the aortic and pulmonic orifice, is one source of information. This comparison is made by listening successively to the second sound as heard in the right and left intercostal space near the margin of the sternum, the sound in the right side emanating from the aortic, and the sound of the left side from the pulmonic orifice. If aortic lesions be indicated by the presence of the aortic direct or regurgitant murmur, and the lesions be of such a character that the aortic valve is impaired, the second sound, as produced by this valve, will be more or less weakened, or perhaps extinguished, and the alteration is ascertained by a comparison with the pulmonic second sound. If, on the contrary, the aortic sound be unimpaired, it may be inferred that the aortic valve is intact. A comparison of the aortic and pulmonic second sound is not less useful in the cases in which mitral lesions are shown to exist by the mitral direct or the mitral regurgitant murmur. If there be much obstruction or regurgitation, or both, at the mitral orifice, the aortic second sound will be weakened by the diminished amount of blood propelled into the aorta with each ventricular systole; and if the mitral obstruction or regurgitation, or both, have led to hypertrophy of the right ventricle, the pulmonic second sound will be intensified by the greater force with which the blood is propelled into the pulmonary artery by the systole of the right ventricle. By means of this beautiful

application of auscultation, thus, useful information is obtained respecting the extent or gravity of the lesions, the existence and situation of which are revealed by the endocardial murmurs.

Further evidence of the extent or gravity of valvular lesions relates to enlargement of the heart. Enlargement of the heart is an effect of valvular lesions, and is proportionate to the amount and duration of the obstruction and regurgitation which the valvular lesions occasion. Hence, the degree of enlargement is a criterion of the extent and gravity of the valvular lesions, and, moreover, the enlargement is a lesion of importance, as has been already seen. The question then arises, How are the existence and degree of enlargement of the heart to be ascertained? The altered situation of the apex, if not attributable to extrinsic causes, is evidence both of the existence and the degree of enlargement. The first effect of enlargement is to carry the apex to the left of its normal situation within the *linea mammalis*. The next effect is to lower its situation to the sixth, seventh, or eighth intercostal space. In proportion as the apex is removed without the left nipple, and lowered, is the amount of enlargement. The situation of the apex is to be determined by the eye or touch, or if it can neither be seen nor felt, by finding the point where the first sound has its maximum of intensity. Other evidence of enlargement is obtained by percussion. The dulness within the area known as the superficial cardiac space, or the space in which the heart is uncovered of lung, is increased in degree and in extent, in proportion as the heart is enlarged. The left border of the heart is found by percussion to fall one, two, or three inches without the left nipple, the situation of the right border, and the base of the heart being, in most cases, but little changed.

Having determined the existence of enlargement and its extent, it remains to ascertain the kind of enlargement, that is, whether hypertrophy or dilatation predominate. The most important signs in this discrimination are furnished by palpation. If either the apex-beat, or additional impulses in the intercostal spaces above the apex, be felt by the hand to be abnormally strong, and especially if there be a heaving elevation of the præcordia with the ventricular systole, hypertrophy predominates. The apex-beat, under these circumstances, may be weak, owing to the globular form which the heart may assume when enlarged; the augmented power of the heart's action is then to be appreciated by the impulses above the apex or by the præcordial heaving. On the other hand, if dilatation predominate, the cardiac impulses, if felt at all, are feeble. Auscultation also furnishes signs of importance in this discrimination. The first sound of the heart over the apex is loud, prolonged, and booming, in proportion as hypertrophy predominates; and, on the contrary, weak, short, and valvular if dilatation predominate. Attention to these points, in connection with the symptoms, will enable the physician to judge of the kind of enlargement to which the valvular lesions have given rise.

Prognosis.—Valvular lesions, not involving either obstruction or regurgitation, may remain for an indefinite period innocuous. The physician should be careful not to attach undue importance to the presence of one or more of the organic murmurs. These are frequently discovered in examinations of the chest when patients complain of no symptoms referable to the heart, and in persons who suppose themselves to be in perfect health. If the lesions be accompanied by enlargement of the heart, obstruction or regurgitation, or both, may be inferred, and the lesions are not innocuous; yet, so long as the enlargement is exclusively or mainly hypertrophic, serious evils directly attributable to the cardiac lesions

rarely occur. The patient, under these circumstances, as a rule, simply suffers more or less inconvenience. The suffering and danger, as already stated, depend chiefly on the weakness arising from dilatation of one or more of the cavities of the heart. The progress of enlargement is generally slow, and it is not uncommon for patients affected with valvular lesions, together with more or less hypertrophy, to live many years, and even to old age.

The symptoms which denote danger, immediate or not remote, differ according to the seat of the valvular lesions. In connection with mitral obstruction and regurgitant lesions, habitual and considerable dyspnœa, if referable to the cardiac affection, that is, not dependent on a coexisting affection such as asthma, is evidence that the fatal termination is not very far distant. The supervention of general dropsy generally shows that the end is near at hand. Yet, sometimes, under judicious management, the dropsy diminishes or disappears, and life is prolonged for a considerable period. Death takes place suddenly in some cases in which the valvular lesions are exclusively mitral, but, as a rule, if life be not cut off by some intercurrent affection, the patient dies after a period of suffering more or less prolonged. In cases of aortic lesions involving obstruction and regurgitation, especially the latter, danger is indicated by the occurrence of paroxysms characterized by great præcordial distress, a sense of impending death, the action of the heart being irregular or tumultuous. Sudden death is liable to occur in paroxysms of this kind, the heart being paralyzed by over-distension of the left ventricle. Sudden death sometimes occurs in cases of aortic lesions when little or no habitual inconvenience from the cardiac affection had been experienced, and the existence of any affection of the heart was perhaps unknown. It is rare for lesions exclusively aortic to lead to general dropsy. The immediate or proximate danger is to be determined by the amount of obstruction or regurgitation, and more especially the latter, in connection with the degree of enlargement, and particularly the enlargement by dilatation.

In cases of tricuspid and pulmonic lesions, general dropsy is an event denoting a degree of weakness of the right side of the heart from dilatation, which will be likely to lead, before long, to a fatal result.

In all cases of valvular lesions, associated with much enlargement, especially if the enlargement be by dilatation, the prognosis is unfavorable; the patient will die sooner or later with the cardiac affection, if life be not destroyed by some other disease, the occurrence of a fatal result being only a question of time, and the duration varying greatly in different cases.

Death may occur in consequence of certain local affections or accidents incidental to the cardiac affection. Thus, pulmonary œdema and pneumorrhagia, due to mitral lesions, may be the immediate cause of a fatal result. Extravasation of blood within the skull may be favored by dilatation of the right side of the heart, and perhaps by hypertrophy of the left ventricle. The loss of blood by hemorrhage from mucous surfaces may, in like manner, lead to a fatal termination. The effects of emboli derived from cavities of the heart are to be included in this category.

Treatment.—The treatment, in cases of valvular lesions, will have reference, *first*, to the condition of the heart as respects these lesions and coexisting enlargement, and, *second*, to the symptoms or events which are incidental to the cardiac affection.

Valvular lesions, so long as they are either innocuous or have not led to enlargement of the heart, claim attention only with regard to prevent-

ing or retarding their progress. And, for this end, the strain upon the valves occasioned by the excessive action of the heart, is, as far as possible, to be avoided. Very active muscular exertions, the excitement of the circulation produced by the abuse of alcoholic stimulants, and violent mental emotions, will be likely to hasten or increase the damaging effects of the lesions. It is, however, by no means necessary to enjoin great restriction in the manner of living in these cases; it is sufficient that the habits of life are governed, in all respects, by prudence and moderation. It is not advisable, under these circumstances, for persons to consider themselves as invalids. If, as is frequently the case, the existence of the lesions be discovered accidentally, or casually, it may not be always judicious to communicate the fact to the patient. If a medical opinion be not requested, and proper hygienic management can be secured without directing the patient's attention to the heart, much needless anxiety is sometimes spared. If, however, information be desired, it should not be withheld, but explanations made which will tend to prevent an over-estimate of immediate danger.

If cardiac symptoms have led the patient to apply to the physician, more or less enlargement will probably be found associated with the lesions. Let it be supposed that the enlargement which exists is mainly due to hypertrophy; it is not desirable to endeavor to diminish this hypertrophy. Inasmuch as whatever obstruction or regurgitation the lesions occasion must continue, the abnormal growth of the walls of the heart is conservative; the comfort and safety of the patient depend upon it, and measures which tend to weaken the heart will do positive harm. On the contrary, measures to maintain the muscular tone and vigor of the heart are indicated. The diet should be nutritious. The appetite and digestion, if impaired, should be improved by tonic remedies. Moderate open-air exercise is to be encouraged, very active exertions being, of course, interdicted. In short, the object is in every way to invigorate and strengthen the system.

If dilatation have taken place, the measures indicated are still those which tend to give, as far as possible, tone and vigor to the heart. The labor of the circulation may be in some degree diminished by restricting the quantity of liquids ingested, redundancy of the mass of blood being in this way prevented. Especial care, however, is to be taken not to impoverish the blood. The diet is to be highly nutritious, although as dry as compatible with comfort; tonic remedies are to be employed, and moderate exercise out-of-doors is still advisable. In proportion as the powers of the system are lowered, the heart is weakened, and dilatation favored. The object of management is, by strengthening and invigorating the system, to retard the progress of dilatation.

Thus far the treatment has reference to the condition of the heart. Of the symptoms incidental to the cardiac affection, irregularity of the heart's action is one which may call for treatment. The appropriate remedies are those which regulate and tranquillize, without weakening, the action of the heart. Digitalis is a valuable remedy, appearing to relieve irregularity of the heart's action without diminishing, but, on the contrary, increasing the power of the ventricular contractions. The conclusion from my own experience accords with that of many observers of late years with respect to this remedy, viz., that, as regards its effect upon the heart, it may properly be called a cardiac tonic. The remedy is, therefore, particularly suited to cases in which the action of the heart is rendered irregular and feeble by dilatation, and it is not suited to cases in which the symptoms and signs denote hypertrophy. Cafeine, or the infusion of coffee, has

measurably a similar effect. Hyoscyamus, belladonna, hydrocyanic acid, and other remedies of the same class, are useful. A belladonna plaster over the præcordia seems to have a good effect. The nauseant sedatives are not to be employed, and the veratrum viride is not appropriate.

Dyspnœa and other pulmonary symptoms are sources of annoyance and suffering in certain cases. So far as these symptoms are dependent on the cardiac affection, all that is to be expected from treatment is palliation. The ethers and mild revulsive applications to the chest or dry cupping may mitigate the dyspnœa. Opiates to check expectoration will be likely to increase the distress instead of affording relief.

General dropsy, in certain cases, is an event requiring treatment. Diuretic remedies should be first tried, and if these prove inoperative, hydragogue cathartics are to be resorted to. Of these, elaterium is the most efficient. Given in small doses, this remedy may often be continued for a long period without producing depression. The bitartrate of potassa with jalap, and podophyllin are valuable hydragogues. In the majority of cases only partial and temporary relief of the dropsy is procured, but in some cases it is completely removed, and it may not return for a considerable period. Diuretic remedies sometimes act very efficiently. They are more likely to effect the absorption of the effused liquid in cases of dropsy dependent on diseases of the heart than in cases of renal dropsy; in the latter cases, the kidneys, being diseased, rarely respond to diuretics. I have known the infusion of parsley-root to act with wonderful power as a diuretic remedy. If the anasarca be extremely great, so that the limbs become enormously distended, numerous punctures may be made with the point of a needle, the punctures being so slight as not to draw blood, and through them a large amount of liquid will sometimes escape, affording, for a time, marked relief. Vesications or cracks in the integument of the lower limbs, in some cases, occur as a consequence of the distension, giving exit to an abundant flow of serum, with relief. Incisions or deep punctures are attended with a risk of being followed by gangrene. In the treatment of the dropsy, restriction of the amount of ingested liquid, as far as is compatible with comfort, is highly important.

A highly important point in the treatment of all cardiac lesions relates to coexisting anæmia. Anæmia is not infrequently associated with the lesions under consideration, and, as a consequence, functional disorder of the heart is superadded to the disturbance caused by the lesions. Irregular action of the heart, or excessive action, dyspnœa, and even dropsy, may be due to the superadded functional disorder. The error is not infrequently committed of attributing the symptoms in such cases exclusively to the lesions, and forming a prognosis more unfavorable than the lesions actually warrant. By removing the anæmia the symptoms are relieved, and the patient may even seem to recover completely from the cardiac affection. Anæmia existing in connection with valvular lesions claims appropriate treatment, viz., removal of the cause if it be apparent, for example, lactation, the employment of chalybeate tonics, with nutritious diet, and other hygienic measures. And such cases call for a certain amount of reserve in referring the symptomatic phenomena to the lesions.

CHAPTER IV.

Enlargement of the Heart without Valvular Lesions. Hypertrophy. Dilatation. Atrophy of the Heart. Fatty Degeneration and Softening of the Heart. Rupture of the Heart. Functional Disorder of the Heart. Enlargement of the Thyroid Body and Prominence of the Eyeballs associated with Functional Disorder of the Heart. Angina Pectoris. Thoracic Aneurism.

IN the small proportion of cases in which enlargement of the heart exists without valvular lesions, hypertrophy and dilatation may be combined, either the one or the other predominating, as in cases in which enlargement proceeds from valvular lesions, or in certain cases, hypertrophy exists without dilatation, and dilatation without hypertrophy. The latter are distinguished as cases of simple hypertrophy and of simple dilatation. These cases do not claim separate consideration; it will suffice to notice, on the one hand, enlargement in which hypertrophy either exists alone or is predominant, and, on the other hand, enlargement in which dilatation predominates.

Hypertrophy is sometimes referable to an obstruction to the circulation, either in the capillaries or at some point in the arterial system of vessels. Thus, hypertrophy of the left ventricle may result from contraction of the aorta and aortic aneurism. Hypertrophy of the right ventricle is a consequence of obstruction in the pulmonary circuit in cases of vesicular emphysema and chronic pleuritis. Hypertrophy of the left ventricle has been supposed to be sometimes due to obstruction to the capillary circulation, incident to certain cases of Bright's disease, and hence the rationale of its occasional association with the latter. In like manner the degenerative changes in the arteries which are liable to occur in advancing age, and the enlarged area of the arterial branches occasioned by corpulency, are supposed to explain the occurrence of hypertrophy. In all these instances the mechanism of the production of the hypertrophy is the same; it is due to long-continued, augmented power of the heart's action.

Mere functional disorder of the heart, under ordinary circumstances, very rarely leads to hypertrophy. Dr. J. M. Dacosta has observed some cases among soldiers during the late civil war, in which hypertrophy, occurring without valvular lesions, seemed to him to be attributable to continued functional disturbance in connection with heavy marching, and especially in soldiers who had recently recovered from fever.[1] I have known hypertrophy to become developed in connection with excessive action of the heart during several years, there being no evidence of valvular lesion, the patient being affected with exophthalmic goitre. Hypertrophy is sometimes found where it cannot be referred to any cause, and it is probably then either congenital or due to an intrinsic tendency in the ventricular walls to an abnormal growth.

The abnormal growth in cases of hypertrophy without, as well as with, valvular lesions varies much in different cases. The walls of the left ventricle at its thickest part, in health, measure in the male about half

[1] *Vide* Sanitary Memoirs of the War of the Rebellion, collected and published by the United States Sanitary Commission, medical volume, edited by Austin Flint, M.D chap. x., p. 360.

an inch, and in the female a fraction less. The walls of the right ventricle are about one-sixth of an inch in thickness at the base. A certain amount of increase is within the limits of health; but the left ventricle, in different cases of hypertrophy, is found to measure from one to two inches, and the right ventricle has a corresponding range of increase. A remarkable specimen of simple hypertrophy, not referable to any obvious cause, and supposed to have been congenital, was exhibited by me to the New York Pathological Society about two years ago. I was indebted for the specimen to Prof. Gilfillan, of the Long Island College Hospital. The left ventricle measured, at its thickest part, $1\frac{5}{8}$ inch, the right ventricle $\frac{3}{8}$ inch. The cavities were not dilated, and the valves were found, by the water test, to be competent. The weight of the heart was $15\frac{1}{2}$ ounces; the average normal weight in the male being 9, and in the female 8, ounces. The subject was a young man aged 23. Death occurred suddenly from congestive apoplexy, the existence of cardiac disease never having been suspected.

The symptoms of hypertrophy are referable to the increased power of the heart's action. Hypertrophic enlargement of the left ventricle leads to an abnormal force of the current in the systemic arteries; the pulse is strong and full, the face flushed, active cerebral congestion is favored, and certain symptoms, such as pain, vertigo, *tinnitus aurium*, are attributable to the latter. The patient feels the powerful action of the heart, but he becomes accustomed to it, and it may occasion but little annoyance. As in the case just referred to, a considerable amount of hypertrophy may exist without symptoms which lead the patient, or others, to suspect the existence of any disease.

If the hypertrophy have been induced by an impediment to the circulation, it is conservative, as when it proceeds from valvular lesions, and is not, therefore, to be regarded as an evil. It may, however, lead or contribute to serious accidents. In the case just referred to, the congestive apoplexy, which proved suddenly fatal, was attributable to no other obvious cause, the organs of the body, with exception of the heart, being free from disease. It is intelligible that hypertrophy of the left ventricle, without valvular lesions (these being, in a measure at least, protective), may favor cerebral hemorrhage in cases in which the arteries of the brain have become weakened from degenerative changes. In like manner, it is not improbable that hypertrophy of the right ventricle may sometimes contribute to pulmonary hemorrhage.

The diagnosis of hypertrophy must rest on physical signs, which are the same as when the hypertrophy is associated with valvular lesions. The fact of enlargement and its degree are determined by the altered situation of the apex-beat, together with the enlarged area of the superficial and the deep cardiac space. That the enlargement is due, either exclusively or mainly, to hypertrophy, is determined by the abnormal force of the impulses of the heart, and by the prolongation, intensity, and booming character of the first sound.[1] The absence of endocardial murmurs is the basis of the conclusion that the enlargement is not connected with valvular lesions.

Hypertrophy, when conservative, or compensatory, of course does not claim treatment. If it be congenital, or there be sufficient grounds for considering it otherwise than conservative, measures to prevent further growth and to obviate accidents are called for. Bloodletting and other measures which impoverish the blood are not indicated. Anæmia, by

[1] *Vide* preceding chapter.

rendering the heart unduly excitable, involves additional inconvenience and danger. If plethora exist, it should be removed by dietetic means and depletion by saline laxatives. Excessive action of the heart may be moderated by tranquillizing remedies, such as aconite, hydrocyanic acid, and belladonna. In the cases of hypertrophy disconnected from valvular lesions observed by Dacosta among soldiers, marked benefit was obtained by the use of aconite, one or two drops of the tincture being given twice or thrice daily, and continued, without any increase of the dose, for months. The diet should be sufficiently nutritious, but unstimulating. Alcoholic stimulants are to be interdicted. Liquids should be taken sparingly. Active muscular exercise and emotional excitement are to be avoided.

Dilatation of the cavities of the heart may follow hypertrophy without, as well as with, valvular lesions. If there be causes giving rise to hypertrophy, which continue after the morbid growth has reached its limit, dilatation of necessity follows, and, in time, will become predominant. But, in most cases, dilatation proceeds from weakness of the muscular walls, arising from fatty degeneration or other causes. The muscular walls may yield to distension, and dilatation take place when there is no abnormal impediment to the circulation; and dilatation, however induced, tends progressively to increase.

The symptoms of dilatation are referable to weakness of the heart's action. This weakness is shown by feebleness of the pulse, coolness and congestive redness of the surface; and, if the right cavities become considerably dilated, general dropsy ensues. Fatal syncope may occur from an over-accumulation of blood in the cavities in cases in which the organ is greatly enfeebled by dilatation. The physical signs show enlargement of the heart; and that the enlargement is due to predominant dilatation is shown by the feebleness of the cardiac impulses, and by the weakness, shortness, and valvular quality of the first sound as heard over the apex. The absence of valvular lesions is inferred from the absence of endocardial murmur.

Of the two lesions, hypertrophy and dilatation, the latter is by far the more serious. The indications for treatment are the same as when the dilatation is in association with valvular lesions, the object, in general terms, being to endeavor to improve the tone and vigor of the muscular walls.

ATROPHY OF THE HEART.

Atrophy of the heart calls only for a passing notice. Reference is had here to wasting of the muscular walls, irrespective of degenerative change, represented, anatomically, by a diminution in weight and volume proportionate to the degree of atrophy. The heart diminishes in size in the progress of chronic diseases attended with great emaciation, for example, tuberculosis. I have met with a specimen, taken from the body of a female dead with chronic pleuritis, in which the weight was reduced to $4\frac{1}{2}$ oz. Atrophy may result from the compression arising from the adhesions following pericarditis, and from the abundant deposit of fat upon the exterior surface. Of course, the muscular power of the organ is diminished in proportion to the degree of atrophy. In a clinical point of view, this lesion is unimportant. As a general remark, it occurs under circumstances which divest it of evil consequences, if, indeed, it be not a conservative provision.

FATTY DEGENERATION AND SOFTENING.

Fatty degeneration is the deposit of oil-drops or granules of fat within the sarcolemma, and the substitution of these for the proper muscular tissue. The pathological character of the lesion has been considered in the first part of this work.[1] An abnormal accumulation upon the surface of the heart of adipose matter and its extension between the muscular fibres, constitute, not fatty degeneration, but fatty growth or obesity of the heart. The accumulation of fat exterior to the sarcolemma may embarrass the heart by its weight, and produce atrophy of the muscular structure by compression; and it may, or may not, be associated with fatty degeneration. Fatty degeneration, if considerable, produces marked changes in the gross characters. The muscular walls present a yellowish or fawn color; the striated or fibrous aspect is obscured; the organ is soft and flabby, and it is easily penetrated or broken down by pressure with the finger. But the microscope furnishes the most conclusive evidence, in the deficiency or absence of the transverse *striæ*, and in the presence of oil-drops or fatty granules in abundance within the sarcolemma. This degenerative change may be general or limited. It may be confined to one ventricle, oftener the left, or to circumscribed patches varying in situation, size, form, and number. The latter, if situated at the exterior, give to the surface a mottled appearance. It may affect the inner layers of fibres, the outer layer being unaffected. The papillary muscles may be particularly affected. Dilatation is often associated with fatty degeneration, the muscular walls either preserving their normal thickness, or the thickness somewhat increased, or again, the walls more or less abnormally thin. Fatty degeneration of the walls of the heart is not infrequently associated with valvular lesions.

In proportion to the degree of fatty degeneration, the heart is, of course, enfeebled, and the symptoms which make up the clinical history of the affection are due to a deficiency of power in the heart to carry on effectively the circulation. Degeneration of the left ventricle occasions feebleness of the pulse. The pulse is apt to be irregular. It has been observed to be notably slow, probably owing to many of the ventricular systoles being too feeble to propel the blood with sufficient momentum to be felt at the radial artery. Dyspnœa, especially on exercise, is more or less prominent as a symptom, according to the feebleness with which the circulation through the pulmonary circuit takes place; this symptom is more marked when the right ventricle is affected. Paroxysms of syncope are liable to occur, accompanied by a sense of præcordial oppression and distress. These denote distension of the cavities from an accumulation of blood. Seizures resembling apoplexy, characterized by temporary loss of consciousness, without paralysis, the surface being pallid and cool and the circulation extremely feeble, have been observed in persons who have subsequently died of this affection. These pseudo-apoplectic seizures, in some cases, have been of frequent recurrence.

Feebleness of the circulation, however, in an equal degree, may proceed from dilatation either with, or without, valvular lesions. The existence of fatty degeneration, therefore, cannot be ascertained positively by means of the symptoms alone. Other circumstances and physical signs are to be taken into account in order to arrive at a diagnosis. The signs which accompany this lesion are, feebleness or absence of cardiac impulse, weakness of the heart-sounds, more especially the first sound, this sound some-

Vide page 47.

times suppressed over the apex, and, if heard, short and valvular like the second sound. These signs are equally present when the heart is considerably or greatly dilated, and they denote fatty degeneration only when the organ is found not to be sufficiently enlarged to refer them to dilatation. The age of the patient is to be considered. Fatty degeneration very rarely occurs in the male under fifty, and in the female under forty years of age. The evident tendency to fatty deposit is another diagnostic point. Fatty degeneration of the heart, it is true, occurs in lean subjects, but it is more apt to occur in those prone to corpulency. The presence of the *arcus senilis* possesses some diagnostic importance, although clinical observation has abundantly shown that this fatty change in the cornea occurs without degeneration of the heart and *vice versâ*. The presence of the *arcus* shows a constitutional tendency to fatty change, and it is significant if signs and symptoms referable to the heart point to degeneration of this organ. The habits of the patient are to be considered with reference to diagnosis. This lesion occurs especially in persons of sedentary or indolent habits as regards muscular exertion, and addicted to the pleasures of the table. The habitual use of alcoholic liquors favors its occurrence. Giving due attention to all the foregoing points, the existence of fatty degeneration may often be determined with much positiveness. If valvular lesions and dilatation be present, its existence is ascertained with less positiveness. Under these circumstances, it is to be suspected when, in addition to the diagnostic points just named, the valvular lesions and enlargement appear to be inadequate to account for the feebleness of the heart's action.

To give rise to symptoms which point to the heart as the seat of disease, the amount of fatty degeneration must be considerable. A small or moderate amount may not occasion sufficient weakness to give rise to any notable symptoms. More or less degenerative change is not infrequently found after death in cases in which it had not been suspected during life. Existing in a small or moderate amount, however, it may constitute an important element in various diseases, rendering the system less able to resist them, and also less able to bear bloodletting and other therapeutical measures which tend to enfeeble the circulation. Existing in a considerable or great amount, it is a grave lesion. In such cases it involves a liability to sudden death. Death may take place from rupture of the ventricular walls. This occurs oftenest in the left ventricle near the apex. In the great majority of the cases of this accident, it arises from softening incident to fatty degeneration. Of 29 cases of sudden death, in persons affected with fatty degeneration, analyzed by Aitken, in 9 the immediate cause of death was rupture. The occurrence of sudden death, when rupture does not take place, is accounted for by over-accumulation of blood within the cavities, and consequent paralysis of the muscular walls from distension.

The objects of treatment, in cases of fatty degeneration, do not embrace recovery from the lesion. The change which has already taken place must continue. The lesion is irremediable. The objects of treatment are to prevent further progress of the degenerative change, and to develop the muscular vigor of the heart to the extent of its impaired capacity for improvement in this respect. The diet should be nutritious, consisting of animal food in as large proportion as is compatible with the appetite and digestion. Fatty food is to be interdicted. Farinaceous and saccharine articles should form a small proportion of the diet. Liquids should be restricted as much as possible. Alcoholic stimulants should be taken in proper moderation. Moderate exercise out of doors is highly

important; it should not be carried, of course, to the extent of overtasking the heart, but taken within the limits of comfort, that is, so as not to occasion hurried circulation, præcordial oppression, or dyspnœa.

The hygienic is far more important than the medicinal management. Yet remedies may be highly useful. Tonic remedies are generally indicated. The appetite and digestion, if impaired, are to be improved as much as possible. If the patient be anæmic, this condition claims appropriate treatment. Coexisting disorders of any kind are to be relieved. The symptomatic effects of weakness of the heart will claim palliative measures. Attacks of syncope and pseudo-apoplexy require ethereal and alcoholic stimulants. Irregular action of the heart may be relieved by hydrocyanic acid and digitalis. The latter appears to act as a direct tonic upon the heart. Dyspnœa, general dropsy, and other effects call for the same palliative measures as when they proceed from dilatation of the heart.

By judicious management, life and comfortable health may be maintained for a long period, notwithstanding the existence of this lesion in a considerable amount.

Softening of the muscular walls of the heart, without fatty or any degenerative change, has been found to occur in the course of typhus and typhoid fever, the eruptive fevers, pyæmia, scorbutus, and other affections. Attention has been directed to its occurrence in typhus and typhoid fever, especially by Louis and Stokes. It may explain the weakness of the circulation disproportionately to the adynamia or general debility in certain cases of these and other diseases. The symptoms and signs are those which represent notable feebleness of the heart's action. As regards the signs, diminished intensity of both sounds, but more especially the first sound, characterizes the feebleness from this as well as other lesions. But a point which is distinctive of softening in the continued fevers, according to Stokes, is derived from the fact that the softening is chiefly of the left ventricle. The first sound, as heard over the apex, is less intense than over the right border of the heart, the sound representing, in the former situation, the force of the systole of the left, and, in the latter situation, of the right ventricle.

Softening incidental to the affections named is due to the disturbance of nutrition which these affections involve. Doubtless, it adds to the danger, but it is not a permanent lesion, the normal condition of the heart being regained if the patient recover from the affection to which the softening is incidental. The existence of softening contra-indicates depletory or debilitating measures of treatment, and, on the contrary, furnishes a reason for supporting treatment, in addition to the indications derived from the condition of the system under which the softening occurs. Without due attention the condition of the heart arising from decomposition after death may be attributed to morbid softening. This error is to be avoided by observing the odor of putrefaction, and by comparing the condition of the heart with that of other organs.

Lesions of the walls of the heart, extremely rare, are due to fibroid formations, extravasation of blood, carcinomatous disease, tuberculous deposit, and acephalocysts. Aneurism of the ventricular walls is another rare lesion. Happily, these belong among the curiosities of clinical experience. They are, of course, grave, but the symptoms and signs to which they give rise are not distinctive; they cannot be made out during life, and hence, their consideration in this work would be out of place. Important lesions of the walls and valves are embraced under the head of

congenital malformations, and connected with these is the affection known as morbus cæruleus, the blue disease, or cyanosis. This affection is to be included among the diseases of infantile life, and is treated of fully in works devoted to these diseases, as well as in treatises on the diseases of the heart. To the latter, and to works on morbid anatomy, the reader is referred for information concerning congenital malformations of the heart.

RUPTURE OF THE HEART.

As already stated (*vide* page 351), this accident is generally incident to fatty degeneration. It occurs, however, as an effect of cardiac aneurism, or myocardiac abscess. It very rarely happens in persons under 70 years of age. Usually it causes instant or speedy death; but, if the perforation be small, it may be temporarily plugged by a clot, and life continue for hours and even days. I have known death to be delayed for six hours after the symptoms denoted the occurrence of the rupture. The symptoms are those which sudden compression of the heart by the accumulation of blood in the pericardium would be expected to produce, together with the loss of blood. In most cases, however, there is no time, before death, for the observation of symptoms. Rupture has been repeatedly observed to occur in connection with a paroxysm of præcordial pains resembling angina pectoris.[1]

FUNCTIONAL DISORDER.

By the term functional disorder is meant disturbed action of the heart, not dependent on either inflammation or structural lesions. The beating of the heart is sometimes morbidly intense. The patient is conscious of its violent action, as when it is temporarily excited by fear or some other powerful mental emotion. This is commonly known as palpitation. The sense of violence may be a subjective symptom only, the force of the heart's action not being actually increased. Generally the action is, at the same time, accelerated and irregular. The irregularity is represented by the pulse, and felt when the hand is placed over the præcordia. The patient is also painfully conscious of it; the organ appears to perform a rolling or tumbling movement, and a sensation is sometimes described as if the heart were in the throat. Intermittency of the heart's action is another feature in certain cases. The action of the heart is, for an instant, arrested; one, two, or three beats are lost, and generally irregularity of action precedes and follows the intermissions. Of these the patient is vividly sensible, and the feeling is that fatal suspension of the heart's action may be liable to take place. These rhythmical aberrations may be accompanied with either violent or feeble action of the heart. The different varieties of functional disorder occur in paroxysms which are very variable as regards severity, frequency of occurrence, and duration. Excessive action of the heart, however, sometimes persists steadily for successive days, weeks, and months. An occasional form of disorder is characterized by every alternate ventricular systole being so feeble as not to be appreciable by a radial pulse, the action of the heart being more or less rapid. On auscultation the two heart-sounds are alternately loud and feeble. I have known this form of disorder to persist for several weeks.

Paroxysmal disorder is quite common. It usually gives rise to great

[1] For an analysis of 24 cases of spontaneous rupture of the heart, by Barth, *vide* Archives Générale de Médecine, Paris, 1871.

apprehension. The patient has a firm conviction of the existence of organic disease, and is in fear of sudden death. It is sometimes difficult to remove this conviction by the most positive assurances to the contrary. Cases of functional disorder are characterized, as a rule, by much mental anxiety and depression, in this respect differing from cases in which disturbed action is due to structural lesions.

The causes of functional disorder are various. It is sometimes attributable to an overplus of red corpuscles of the blood or plethora. As incident to this condition, it occurs in persons addicted to the pleasures of the table, digesting and assimilating actively, and taking but little active exercise. It is much oftener, however, associated with the opposite condition, viz., anæmia. Anæmic persons are rarely exempt from more or less disturbance of the heart's action. It may be produced by long-continued mental anxiety or depression. It is apt to occur in persons of an anxious, worrying disposition, and in those who are constitutionally disposed to melancholy. The effect which it produces on the mind reacts on the disorder, and tends to perpetuate it. It appears, in some cases, to be dependent on indigestion or dyspepsia, and paroxysms are apt to be excited by dietetic errors. The use of tobacco gives rise to it in some persons, so, also, strong tea, or coffee. It is incidental to the gouty diathesis. The exhaustion following prolonged mental excitement and physical exertions may be accompanied by it. It prevailed to a great extent among soldiers during the late civil war, excessive and persistent palpitation often leading to discharge on the ground of disability from supposed organic disease of the heart. Excessive venery and habits of self-abuse are to be included among the causes. The associated symptoms will, of course, vary according to the different circumstances under which it occurs.

It is extremely desirable, in view of the comfort and welfare of the patient, to determine with positiveness, in cases of functional disorder, that structural lesions do not exist. Several points, connected with the history and symptoms, have a bearing on the diagnosis. The occurrence of the disturbance in paroxysms, the action at other times being regular; the paroxysms occurring at night rather than in the daytime, and frequently not being occasioned by any obvious cause, such as muscular exertion or mental excitement; the ability of the patient to take active exercise without palpitation or dyspnœa when not suffering from the disorder, and the intensity of mental anxiety and apprehension, are points which render it probable that the difficulty is purely functional. These points, however, are not conclusive. A positive diagnosis is to be based on the exclusion of lesions of structure by the absence of the physical signs of the latter. If, on a careful examination of the chest, the heart be not found to be enlarged; if there be no murmur present, or if an existing murmur be inorganic, and the heart-sounds be normal, the affection may be confidently pronounced functional. Without the negative proof afforded by physical exploration, the mind of the practitioner must be in doubt as to the diagnosis. If he give a decided opinion, it is a guess which may prove to be either right or wrong. If he avoid giving a decided opinion, the inference which the patient usually draws is, that organic disease exists, and that the physician is reluctant to tell him the truth. I could cite, from the cases which have come under my observation, not a few in which patients were for many years rendered unhappy and deterred from engaging in the active duties of life, by either an erroneous medical opinion that they had organic disease of the heart, or by a fixed belief that such was the fact, based on the indecision of their physicians.

The curative treatment of functional disorder must have reference to the circumstances with which it is connected. Occurring in connection with plethora, the measures indicated are, restriction of diet, change of habits as regards exercise, depletion by saline laxatives and perhaps by small bloodlettings. Occurring in connection with anæmia, measures of precisely an opposite character are indicated, viz., those designed to restore the normal condition of the blood. An investigation with reference to the source of the disorder is to be made in all cases, and the causes, if apparent, are to be obviated. If connected with dyspeptic ailments, these are to be remedied by appropriate treatment; and so if dependent on the gouty diathesis, this will claim suitable remedies. In the great majority of cases, the proper treatment consists of tonic remedies, a nutritious, regular diet, regularity of habits as regards excesses of all kinds and a proper amount of sleep, the interdiction of tobacco, strong coffee and tea, and out-door exercise with mental recreation; in short, an invigorating system of hygiene. Positive assurances of the absence of organic disease, such as may be given if based on the absence of all the physical signs of lesions, will often go far toward effecting a cure, the disorder being frequently kept up by mental inquietude occasioned by the fear of sudden death.

During the paroxysms palliative measures are called for. These consist of ethereal stimulants, anti-spasmodics, and occasionally opiates, with sinapisms or stimulating liniments to the chest. If paroxysms occur frequently, a belladonna plaster may be constantly worn over the præcordia. Blisters or other severe counter-irritants are never requisite. Small doses of aconite are useful if the action of the heart be violent, and, on the other hand, if the action be feeble and irregular, digitalis may prove of use.

Some persons are strongly predisposed to disturbed action of the heart, and suffer, more or less, from functional disorder for many years, or during their whole lives. The mental anxiety in such cases after a time ceases, and patients become reconciled to this as to other physical evils. The frequent recurrence of functional disorder for an indefinite period does not lead to the development of organic disease. The physician is fully warranted in giving positive assurance to the patients on this point.

In the foregoing remarks on functional disorder, it has been assumed that structural lesions are not present. But functional disorder and lesions may be associated when the former is not dependent on the latter; in other words, the causes which give rise to functional disorder when the heart is free from lesions will produce the same effect when cardiac lesions exist. It is highly important for the practitioner to appreciate this fact. Not infrequently the disturbance of the heart's action, in cases in which organic murmurs are found, is mainly or exclusively functional. It is not uncommon for practitioners to err in considering all the symptoms referable to the heart as arising from organic lesions if these exist in ever so small an amount. Anæmia, coexisting with trivial lesions, may occasion greatly disturbed action of the heart, with dyspnœa and even general dropsy, so that the patient may seem to be in the last stage of cardiac disease, and, if the anæmia be cured, the recovery appears to be complete. It should always, therefore, be a question, in cases of organic lesions, whether more or less of the symptomatic phenomena may not be due to functional disorder arising from anæmia, deranged digestion, or a morbid condition of the nervous system produced by tobacco, coffee or tea, mental depression, excessive venery, or gout. This question is to be decided in the affirmative when causes of functional disorder are discoverable, and

when the amount of the organic affection, as determined by the physical signs, appears to be insufficient to account for the symptomatic phenomena. In proportion as the latter are fairly attributable to functional disorder, the prognosis is, of course, less grave, and improvement may be expected from appropriate treatment.

ENLARGEMENT OF THE THYROID BODY AND PROMINENCE OF THE EYEBALLS (EXOPHTHALMIC GOITRE) ASSOCIATED WITH FUNCTIONAL DISORDER OF THE HEART

Within the last few years, the attention of clinical observers has been directed to an affection characterized by enlargement of the thyroid body and prominence of the eyeballs, conjoined with inordinate action of the heart. These three pathological events form a striking combination, giving to the affection a well-marked individuality. In the absence of a name expressive of its character, a German author, Hirsh, applied to it the name Basedow's disease, after a German observer, who was among the first to describe it fully; and the distinguished clinical teacher, Trousseau, in view of the prior claim of the late Dr. Graves, proposed to call it *Graves' disease*. The three events just named evidently have some pathological connection, the nature of which is not yet fully understood.

The prominence of the eyes is the most remarkable of the triple events. Existing, in some cases, in a marked degree, it gives to the countenance a peculiar expression. The projection of the globes displays more or less of the tunica albuginea, and the patient has a ferocious, staring look which, existing in both eyes, is at once diagnostic. The projection is sometimes so great as to prevent closure of the lids, and the eyeballs are partially exposed during sleep. Vision is generally not impaired, and the appearance of the eyes, aside from the prominence, is natural. The condition of the eyes does not involve pain, but the patient sometimes feels as if the eyeballs were being squeezed out of the sockets. The thyroid body is more or less enlarged, the enlargement being usually greater on the right side. The increase does not go on indefinitely, forming the immense tumors which are sometimes seen in cases of ordinary bronchocele or goitre, but ceases after a moderate or considerable augmentation of bulk has been attained. The swelling does not give rise to pain, but it may occasion some obstruction to respiration from pressure on the trachea, and may lead to embarrassed breathing and modification of the voice by interfering with the function of the recurrent laryngeal nerve. The thyroid arteries are enlarged, and a strong pulsation is felt over these and the carotids, frequently accompanied by marked thrill. Arterial and venous murmurs, frequently loud and sometimes musical, are heard when the stethoscope is placed over and near the enlarged thyroid body.

A morbidly increased activity of the heart is a constant and notable feature. In some cases this amounts to a persisting palpitation. This functional activity is increased in paroxysms. The beats are morbidly accelerated, the pulse varying from 100 to 140 beats per minute. Valvular lesions and enlargement of the heart exist in some, but not in all, cases. When they are present they do not account for the functional disorder. Loud inorganic murmurs at the arterial orifices of the heart are not infrequent. The inordinate action of the heart may continue persistingly for months and even years.

More or less anæmia coexists generally, but not invariably. This has been by some considered as an essential pathological element of the affec-

tion. The anæmia is usually marked. Other symptoms which have been noted are, mental depression and irritability, inability to sleep, amenorrhœa, abnormal increase of appetite followed by anorexia, sometimes hysterical phenomena, and emaciation. The affection is essentially chronic. In the majority of cases it continues for months and years. It does not seem to tend intrinsically to a fatal result, but patients are apt to be cut off during its continuance by some intercurrent affection. Recovery takes place in a certain proportion of cases, the improvement being slow, and some degree of enlargement of the thyroid body and prominence of the eyes remaining permanently.

The affection is rare, and, since the attention of clinical observers has been directed to it only within the few past years, further materials for its clinical history are yet to be gathered. I have notes of only seven cases. In three of these the patients were only temporarily under my observation. Of the four remaining cases the facts relating to the progress and termination were briefly these.[1] In one case, that of a girl 16 years of age, the affection, although distinct, was slight as regards the enlargement of the thyroid bodies and the prominence of the eyes. It nearly disappeared, and she was married at the age of 22. She died three years after her marriage, having been recently confined. The only facts learned respecting her last illness were that she was dropsical; that there was difficulty of breathing, and that she was said to have disease of the heart. In another case the patient was under observation, from time to time, at the Bellevue and the Charity Hospitals, during eight years. At first there was no evidence of organic disease of the heart. Subsequently, considerable hypertrophy became developed. The prominence of the eyes and the enlargement of the thyroid body became much less than at first, but she very gradually declined in strength, became greatly emaciated, and died by exhaustion. The heart weighed 20 oz., and there was no valvular lesion. The lungs were emphysematous, and the kidneys presented fibroid degeneration. In a third case the patient, a female aged 29, was under my observation for three years. The prominence of the eyes, which was very marked, continued, but the enlargement of the thyroid bodies had disappeared. The pulse was 140. There was no material change during the time she was under my observation. In the fourth case, a female aged about 40, the affection had existed for ten years, and she had notably improved as regards the prominence of the eyes, the thyroid enlargement, and the rapidity of the pulse. She came under my observation in an attack of pneumonia which proved fatal apparently from heart-clot.

The pathological character of the affection is not established. That the three pathological events are due exclusively to anæmia is hardly probable, since anæmia is sufficiently common without these events, and, moreover, there is not always coexisting anæmia. According to Trousseau, the anæmia in some cases does not occur until after the development of the affection. Trousseau and others have considered it as one of the functional affections of the nervous system or the neuroses. The enlargement of the thyroid body seems to be due to abnormal vascularity and hypernutrition. The prominence of the eyes is not due to enlargement of the globes. In some of the few autopsical examinations which have been reported, an abnormal amount of areolar and adipose tissue has been found at the bottom of the orbit. But that the protrusion is not always due to this cause is shown by the fact that it has been observed to cease

[1] For a fuller account of three of these cases, *vide* my work on the Diseases of the Heart, second edition, 1869.

after death; and during life, in certain cases, moderate pressure suffices to restore the globes to their normal situation. It has been attributed to a relaxed condition of the recti muscles, and to congestion of the vessels behind the eyeballs. The prominence of the eyes and enlargement of the thyroid body are consecutive to the cardiac disorder.[1] Cases are observed in which enlargement of the thyroid body is conjoined with inordinate functional activity of the heart, without prominence of the eyes, and Trousseau cites a case in which the two latter were associated without enlargement of the thyroid body. An example of the latter has fallen under my observation. In my case the prominence of the eyes nearly disappeared in a year after the patient first consulted me. Mitral stenosis existed in this case. The affection, in the great majority of cases, occurs in females. Of fifty cases collected by Wilthuisen, a Danish author, only eight were male subjects.[2] Of my seven cases, in all, save one, the patients were females.

The indications for treatment relate to the functional disorder of the heart, together with the morbid state of the nervous system and the coexisting anæmia. Sedative remedies which tranquillize the action of the heart without producing depression or interfering with the appetite and digestion, are indicated. For this end, hydrocyanic acid, aconite, belladonna, and digitalis may be employed. The anæmia calls for tonic remedies, and especially ferruginous tonics; the latter have seemed to be beneficial in the cases which I have observed. Arsenic has been found useful. Iodine, with reference to the affection of the thyroid body, is of doubtful utility. Hygienic measures are probably of greater importance than remedies. Freedom from mental depression is to be secured as far as possible, and, whenever practicable, change of scene and other means of mental recreation are advisable. The diet should be nutritious, and outdoor life is desirable. Trousseau advocates the employment of cold water after the hydropathic method.

ANGINA PECTORIS.

The affection known as angina pectoris is essentially neuralgic, and might, therefore, be included among the diseases of the nervous system. It is considered here on account of its frequent connection with cardiac lesions and with notable disorder of the heart's action. In the previous editions of this work a distinction was made between true angina and pseudo-angina, the former being the neuralgic affection associated with cardiac lesions, and the latter a neuralgia occurring independently of any disease of the heart. This distinction, although based on a point of difference of great practical importance, seems to me pathologically incorrect, and, therefore, in the present edition I shall cease to use the term pseudo-angina, embracing this purely neuralgic affection under the name angina pectoris, and expressing the distinction by saying angina with, and angina without, cardiac disease. The following description will relate to typical cases in which the angina is associated with disease of the heart.

The affection is characterized by pain, usually intense, burning, tearing, or lancinating in character, emanating from the præcordia or beneath the sternum, and radiating thence in different directions, viz., into both sides

[1] For the facts bearing on the theory that this affection depends on a lesion (hypertrophy of connective tissue and atrophy of nervous substance) of the lower conical ganglia of the sympathetic nerve, *vide* prize essay on the ganglionic nervous system, by Robert T. Edes, M.D. Trans. N. Y. Acad. of Med., 1869.

[2] Trousseau, Clinique Médicale, tome ii.

of the chest, the back, and frequently the left shoulder; extending down the arm and sometimes to the forearm; occasionally felt in the forearm and hand and not in the shoulder and arm; in some cases extending more or less into both upper extremities, and it has been known to extend into one and both of the lower extremities; and, finally, it may shoot upward into the neck, temples, and jaws. Different cases differ much as regards the intensity of the pain and the situations, among those just named, in which it is felt. The pain in some cases is so intense as to be truly excruciating, and is accompanied by a feeling of constriction of the chest; in other cases it is moderate, or even comparatively slight.

The affection is paroxysmal, and the pain is but one of the elements which enter into the paroxysm. The action of the heart is generally more or less disturbed. The beats are irregular, sometimes violent or tumultuous, and sometimes feeble. In some cases the pulse is notably slow. An indescribable anguish or "heart-pang" is another element. A vivid sense of impending death is felt. The paroxysm is usually developed suddenly, and the patient is compelled instantly to remain perfectly still; he is apprehensive of making the slightest movement, and seizes hold of some firm support in order to maintain a fixed position. He is afraid to breathe freely, although the power of doing so is not lost. Dyspnœa does not belong to the paroxysms save in so far as it may depend on existing cardiac lesions, and is due to voluntary restraint of the respiratory movements. He is perhaps afraid to speak. A sense of numbness is felt in the parts into which the pain extends. The countenance denotes anxiety and suffering. The surface is generally pallid, cool or cold, frequently bathed in perspiration, and sometimes cyanosed or livid.

Cases differ greatly as regards, not only the severity of the paroxysms, but their duration and the frequency of their recurrence. They usually last for a few moments only, but in some cases they continue for several hours. They may recur at wide intervals or frequently. As a rule, to which there are a few exceptions, if a paroxysm have been once experienced, other paroxysms will follow sooner or later. Generally they become progressively more and more frequent, if the life of the patient continue. At first, and for some time, they appear to be excited by some notable cause, such as unusual muscular exertion or a powerful mental emotion, but, after a time, they are liable to occur from trivial causes and without any apparent cause. They are sometimes produced during sleep apparently by distressing dreams.

The affection, as thus described, is incidental generally to organic disease of the heart or aorta, but, so far as at present known, not with any one form of lesion. It is much oftener associated with lesions at the aortic than at the mitral orifice, yet it occurs in only a very small proportion of the cases of aortic lesions. It occurs in some cases of fatty degeneration of the heart without any valvular lesions. It is sometimes associated with aneurism of the aorta. It has been observed in cases in which the coronary arteries are obstructed by calcification or other lesions, but this is not essential to its occurrence, as was at one time supposed. It is an affection of rare occurrence. Of over 150 cases of organic disease of the heart which I analyzed in 1859, it occurred in only 7; and it occurred in 8 out of 188 additional cases analyzed in 1869. That it has a pathological connection with organic disease of the heart is certain, but upon what particular condition or circumstance common to different forms of organic disease it depends is not ascertained. This statement applies more particularly to the pain or neuralgic element of the paroxysms. The other elements may perhaps be satisfactorily explained.

Angina pectoris, when associated with diseases of the heart, involves liability to sudden death. Death may take place suddenly, in a paroxysm. The most reasonable way of accounting for the sudden death, as it seems to me, is to attribute it to over-accumulation of blood within the ventricular cavities, and arrest of the heart's action as a result of paralysis from distension. The explanation, in fact, is the same as of sudden death in cases of free aortic regurgitation, and fatty degeneration. The liability to sudden death, if this be the correct explanation, characterizes cases in which the coexisting organic disease is of a kind to favor sudden over-accumulation of blood in the cavities. Aortic lesions and fatty degeneration have this effect. If the lesions do not lead to this effect, patients rarely die suddenly, but linger on for an indefinite period with the recurrence of the paroxysms more or less frequently. Moreover, the overloading of the cavities of the heart will account for elements of the paroxysms other than the pain, viz., the disturbed action of the heart, the indescribable anguish, and the sense of impending death. If the lesions to which the angina is incidental be not of a character to lead to overloading and consequent distension of the ventricular walls, the suffering is mainly from the pain. Some cases of angina are of this description, very little disturbance of the heart's action accompanying the paroxysm. On the other hand, all the elements of a paroxysm of angina, except the pain, are observed, not infrequently, in cases of aortic lesions with regurgitation; and sudden death is liable to occur in the paroxysms of distress to which patients affected with these lesions are subject, the paroxysm lacking only pain to constitute angina pectoris. The prognosis in cases of angina is always grave if physical signs show the existence of serious cardiac lesions; and sudden death is to be expected if there be much aortic regurgitation, or the habitual weakness of the heart render probable fatty degeneration or impaired nutrition of the organ. The danger, it is to be observed, is not to be measured by the intensity of the pain: it is not the pain which kills, but the coexisting organic disease.

Angina pectoris, in so far as the neuralgic element is concerned, undoubtedly occurs without any evidence of coexisting disease of the heart or the aorta. Several examples have fallen under my observation. In these cases the paroxysms generally lack those elements which are derived from cardiac lesions. The necessity of keeping a fixed posture, while the paroxysm lasts, is not felt in the same degree; the patient may writhe with pain, and try frequent changes of posture with the hope of obtaining relief. The sense of impending death is less, or wanting. There is little danger of sudden death, and the prognosis, as regards recovery, is favorable. These points are to be considered in the differentiation of these cases from those in which the angina is connected with disease of the heart; but the absence of cardiac lesions is determined by the negative result of a careful physical exploration of the chest.[1]

[1] For a fuller consideration of angina pectoris, see my work on Diseases of the Heart, second edition, 1869. The knowledge of the functions of the pneumogastric nerve, acquired by means of late experimental researches, explains the disturbance of the heart's action in certain cases of angina. The effect is analogous to that of galvanism transmitted through this nerve. Through this effect sudden death may take place irrespective of cardiac lesions. This statement is not in accordance with what was stated in the previous editions of this work. But I have met a case in which sudden death occurred in a paroxysm, and cardiac lesions sufficient to account for the death were not found on post-mortem examination. The danger of death during a paroxysm may be estimated by symptoms denoting the degree of the disturbance of the heart's action, namely, by the slowness, feebleness, and irregularity of the pulse, taken in connection with the feeling of impend-

The treatment embraces measures to afford relief in the paroxysm, and those indicated in the intervals. The palliative measures embrace opium, given promptly and sufficiently to relieve the pain. It should be given in a form to act as speedily as possible. The hypodermic method, if the physician happen to be at hand, is to be preferred. Alcoholic, ethereal, and other stimulants are indicated in proportion as the action of the heart is irregular and feeble. Revulsive applications to the chest and extremities are appropriate. Swallowing pieces of ice has been found effective. Recently the nitrite of amyl has been introduced as a remedy for arresting the paroxysms. Cases have been reported by trustworthy observers in which it has proved very promptly and completely efficacious. It is to be given by inhalation. Great caution is requisite in its use. Five drops may be inhaled from a handkerchief held over the nostrils. In two cases under my observation the relief has been immediate and complete whenever a paroxysm has occurred. It produces a sense of fulness in the head, with flushing of the face, increased frequency of the heart's action, and a sense of general relaxation. These effects are of transient duration. The remedy may be repeated at intervals during the same day, should there be recurrence of the paroxysms.[1]

The inhalation of ether or of chloroform is to be enumerated among the resources for arresting the pain, or mitigating its severity. The inhalation of chloroform should not be resorted to if the action of the heart be feeble. In the intervals, the first point is to avoid, as far as possible, everything which will be likely to provoke a paroxysm, such as active exercise, mental excitement, over-ingestion of food, and the abuse of alcohol. Aside from prophylaxis, the measures indicated are those which have reference to the causes of neuralgia, to the general health, and, in the majority of cases, to coexisting organic disease of the heart or aorta. Anstie has found arsenic, in small doses long continued, extremely useful in preventing the paroxysms.[2] Trousseau, who regarded the affection as analogous to epileptic seizures, and called it *cardiac epilepsy*, advised the long-continued employment of belladonna. Electrization of the surface within the præcordia has been found useful both in arresting the paroxysms and postponing their occurrence.

THORACIC ANEURISM.

Referring the reader to works which treat especially of diseases of the heart and aorta, and to surgical treatises, for an account of the different varieties of aneurismal tumors, of the modes in which they are produced, etc., I shall simply enumerate the diagnostic symptoms and signs of aneurism of the thoracic aorta, with the prognosis and treatment, limiting the term aneurism to a circumscribed dilatation of the vessel, forming a tumor of greater or less size. Aneurismal tumors may spring from the thoracic aorta at different points. Not infrequently they originate within the pericardium, in the sinuses of Valsalva, and, in this situation, rupture takes place before the tumor attains to great size, the hemorrhage taking place into the pericardial sac, and, of course, causing instant death. A fatal

ing danger. These symptoms, of course, denote a far greater amount of danger when cardiac lesions coexist which in themselves involve more or less danger of sudden death, namely, free aortic regulation, with dilatation of the left ventricle, and fatty degeneration. Note to fourth edition.

[1] *Vide* articles by Prof. H. C. Wood in Am. Jour. of Med. Sciences, July and October, 1871.

[2] On Neuralgia, etc., 1872.

result from aneurism in this situation generally occurs without any diagnostic symptoms, and without any symptoms denoting a grave disease. The diagnosis is very difficult and perhaps impossible. Of 703 cases analyzed by Dr. Sibson (*Med. Anatomy*, fasc. v.), 87 were within the pericardium. The ascending portion of the arch without the pericardium is the most frequent site; in 193 of the 703 cases analyzed by Dr. Sibson, the situation was in this portion. The ascending and transverse portions are not infrequently both involved in the dilatation. This was the case in 140 of 703 cases. The transverse portion was affected alone in 120 cases, and, conjointly with the descending aorta, in 20 cases. The descending portion of the arch was the seat in 72, and the aorta below the arch in 71 cases.[1] The aneurismal tumors in the larger proportion of cases spring from the outer aspect of the artery, but they may spring from either the inner, posterior, or anterior aspect.

Aneurismal tumors, according to their situation and size, give rise to certain symptoms by pressing upon the different surrounding parts. Unless referred to their true source, these symptoms may mislead the physician by appearing to indicate other affections. And by means of these symptoms, not only may aneurism be suspected, but, assuming its existence, its situation may be inferred.

Interruption of the circulation through the innominata and the left carotid and subclavian artery may arise either from the pressure of the tumor on these vessels or obstruction by fibrinous plugs. Feebleness or extinction of the pulse in the radial, brachial, or carotid artery on one side is one of the symptoms of aneurism, and indicates its situation to be at the right or left extremity of the transverse portion of the arch. When the radial pulse is not abolished, but more or less weakened, the contrast between the pulse of the two arms is well shown by a comparison of the visible characters as traced by the sphygmograph. Niemeyer has called attention to a notable retardation of arterial pulsations beyond the seat of the aneurism. Thus, when the aneurism is seated between the points of origin of the great vessels of the arch of the aorta, the radial pulse is felt later on one side than on the other; and, if the aneurism be seated in the descending aorta, the pulsations of the arteries below occur later than the pulse at the wrist. An aneurismal tumor springing from the ascending or transverse portion of the arch may press upon the superior vena cava or the venæ innominatæ, and induce venous congestion limited to the head and upper extremities, or to one upper extremity, accompanied, perhaps, by more or less œdema. These symptoms point to the existence and situation of aneurism.

An aneurism seated in the transverse portion of the arch may press upon the trachea or one of the primary bronchi, and interfere with respiration. If the obstruction be considerable, the breathing is labored, and may be accompanied with a noise, heard at a distance, called stridor. Under these circumstances, auscultation will show feebleness of the respiratory murmur on both sides of the chest if the trachea be pressed upon, but feebleness limited to one side, and the murmur exaggerated on the other side, if only one of the bronchi be obstructed. Embarrassment of respiration may proceed from pressure upon another part, viz., the recurrent laryngeal nerve. If the pressure be sufficient to interrupt the function of the nerve on one side, laryngeal obstruction arises from an arrest of the respiratory movements of the glottis on that side. The embarrassment from this cause, however, is not very great. The laryngoscope in

[1] Fuller, on Diseases of the Chest.

these cases shows the vocal chord on one side to be motionless, that is, paralyzed, while the respiratory movements of the other chord continue. Spasm of the glottis may be induced if the relation of the nerve to the tumor be such that it is irritated instead of its function being annulled. I have reported a case in which, the left recurrent nerve being situated between a calcareous deposit and the aneurismal tumor, spasm of the glottis occurred so frequently and to such an extent as to prove fatal.[1] Modification of the voice and aphonia are effects of either incomplete or complete paralysis from pressure on the recurrent laryngeal nerve, and the affection of the voice is found to vary at different times according to the varying amount of pressure. These laryngeal symptoms are apt to mislead by directing attention to the larynx as the seat of disease. Tracheotomy has been repeatedly performed under the belief that the obstruction of respiration was due to an affection of the larynx. My colleague, Prof. McCready, has given me the account of a case in which the primary and most marked effect was manifested by vomiting and pyrosis, an examination after death showing that the tumor pressed upon the pneumogastric nerve.

Pressure on the œsophagus, when the tumor is situated in the transverse or descending aorta, may occur so as to occasion obstruction to the passage of food. This symptom should excite suspicion of aneurism, and such a suspicion should enforce caution in the use of bougies to explore and dilate the œsophagus. Pressure on the thoracic duct has been known to occur, inducing marked emaciation. Pressure on the sympathetic nerve is another effect of an aneurismal tumor, leading to contraction of the pupil of the eye on the affected side. If the tumor be seated in the descending aorta, it is likely to lead to erosion of the vertebral column, and may thus occasion paralysis by affecting the spinal cord. These cases are generally characterized by considerable pain referred to the back. Neuralgic pains and well-marked angina pectoris sometimes accompany aneurism seated in the ascending aorta.

The diagnosis of thoracic aneurism is to be based on the presence of more or less of the foregoing symptomatic phenomena, taken in connection with the physical signs of a tumor within the chest, situated at some point in the tract of the aorta. The signs are very obvious when the aneurism has led to erosion of the ribs and an external tumor, pulsating, perhaps presenting a thrill, the heart-sounds heard with more or less intensity when the stethoscope is placed over it, with a single or double bellows murmur. The signs are less marked before the tumor makes its way through the thoracic walls, but they may be sufficient to render the diagnosis quite positive. Dulness on percussion over a circumscribed space in the tract of the aorta is an important diagnostic point. This space will be on the anterior surface of the chest, if the aneurism spring from the arch, and posteriorly if it spring from the descending aorta below the arch. Careful inspection and palpation may disclose pulsation and perhaps thrill before any external tumor is apparent. Undue audibleness of the heart-sounds within the space found to be dull on percussion, and a single or double murmur not transmitted from the aortic orifice, are highly significant signs. They are, however, by no means uniformly present, and, therefore, while their presence contributes to the diagnosis, their absence is not proof that aneurism does not exist.

The prognosis, in cases of thoracic aneurism, relates chiefly to the duration of life. The instances of recovery are so few that practically they

[1] American Medical Times, 1864.

are to be disregarded. In the majority of cases, death is the result of rupture of the aneurismal sac. The rupture may take place in various directions, viz., externally, or into the œsophagus, trachea, bronchi, pleural cavity, heart, venæ cavæ, spinal canal, pericardial cavity, etc. The rupture may be at first small, so that death takes place more or less gradually; or it may be large enough to cause a sufficient hemorrhage to destroy life within a few moments. The progress of the aneurism varies much in different cases, the duration of life being in some cases but a few months, and in some cases several years. In a considerable number of cases life is destroyed before rupture takes place. Pressure on the trachea, œsophagus, vena cava, thoracic duct, or irritation of the recurrent laryngeal nerve, may lead to a fatal result, and the patient may be cut off by some intercurrent affection. Organic lesions of the heart coexist in a certain proportion of cases. These, of course, involve distress and danger in proportion to their nature and extent, and may prove the immediate cause of death. Clinical observation shows that patients affected with thoracic aneurism rarely have pulmonary tuberculosis.

The treatment relates to the palliation of suffering and the prolongation of life. All active exertions are to be avoided, and, as far as possible, emotional excitement. The body is to be well nourished, if possible, but the diet should be unstimulating, and alcoholic stimulants interdicted. Liquids should be taken sparingly. The action of the heart, if abnormally strong, is to be diminished by sedative remedies, and perhaps, if the patient be plethoric, in some cases, by small abstractions of blood. It is highly important not to impoverish the blood, and anæmia, if it exist, calls for the treatment appropriate to that condition. Pain and other incidental symptoms are to be palliated by appropriate remedies.

It is well to bear in mind that the progress of the aneurism is retarded by the deposit of successive layers of fibrin within the aneurismal sac. It is in this mode that a cure sometimes takes place. It is desirable, therefore, that the blood should be rich in fibrin, and it is probable that the deposit is more likely to take place in proportion as the action of the heart is slow. Cardiac sedatives, namely, aconite, digitalis, and the veratrum viride, may in this way be useful. Certain remedies have been supposed to have a more direct curative effect in some cases of aneurism; and experience has seemed to furnish evidence of such an effect. The acetate of lead and the iodide of potassium, more especially the latter, are remedies which have lately been so considered. Roberts, of Manchester, England, Balfour, of Edinburgh, Bouillaud, and others, have reported cases in which the iodide of potassium, given in doses of from 15 to 95 grains daily, appeared often to be useful, and sometimes to effect a cure. It is difficult to understand how these or other remedies can exert a direct curative influence in any other way than by promoting the deposit of fibrin in stratified layers which adhere to each other and the inner surface of the aneurismal sac. It is claimed that the remedies first named do exert a curative influence in that way; their therapeutic value remains to be determined. The long-continued use of the acetate of lead is objectionable; but the iodide of potassium may be tried sufficiently without risk of evil consequences. In a case of aortic aneurism which has fallen under my observation, diminution of the size of the sac, with notable relief of pain, has followed the use of the iodide of potassium in doses of grs. xxx, three times daily.[1]

[1] Since this sentence was written I have witnessed apparent benefit from this remedy in several hospital cases, although in no instance has a cure been effected. —*Note to 4th Edition.*

If spasm of the glottis be induced, through the recurrent laryngeal nerve, to such an extent as to endanger life, laryngotomy is warrantable, if not advisable, with a view to palliation and the prolongation of life. This operation will, of course, be of no avail if the obstruction be due to pressure of the aneurismal tumor upon the trachea.

A half century or more ago a plan of treatment was devised by two Italian physicians, Albertini and Valsalva, for the cure of aneurisms. This plan embraced entire physical rest, frequent and copious venesections, and reduction of food to the lowest point compatible with life. Although sanctioned by Laennec, Bouillaud, and Hope, this course was never generally adopted, and for several years has been obsolete. A reproduction, in part, of this plan was proposed by the late Dr. Bellingham, and Joliffe Tuffnell, of Dublin, has reported a series of cases which show a remarkable success from it. Tuffnell does not employ bleedings, but he requires perfect rest in a recumbent position for two or three months, the patient during this time not raising himself even to the semi-recumbent posture, but he is allowed to turn carefully from side to side, and at times to lie on the face to relieve the back. He is to be in a sunny room, where he can have some range of observation, and is to be amused as far as practicable. The diet is to consist of two ounces of white bread and butter for breakfast; the same for supper, with two ounces of milk, or cocoa or tea, and for dinner three ounces of boiled or broiled meat, with three ounces of potatoes or bread, and four ounces of water or claret. The diet is to be rigidly restricted to the articles and quantities just stated. Under this plan of treatment Tuffnell claims to have cured five or six cases of aortic aneurism, in one, the tumor having projected through the sternum.

Dr. Henry J. Bowditch suggests, as a modification of Tuffnell's plan, venesection in some cases, and less reduction of the daily allowance of food, the chief reliance being placed on absolute rest in the horizontal position.[1]

I have had under observation four cases in which "Tuffnell's plan" was employed. In none of these cases was the plan successful, although in all it seemed to be more or less useful.[2] I should have resorted to the plan in a larger number of cases, were it not that it is difficult to secure the complete and continued co-operation of the patient. The merits of the plan are, of course, to be determined by further experimental observation; and, for this end, reports of cases in which it has been faithfully carried out under the direction of competent and trustworthy observers, are desirable.

Measures desired to produce directly coagulation within the aneurismal sac have been to some extent employed, namely, the injection of astringent liquids, the introduction of solid substances, and the application of the electrical current by means of needles introduced within the sac. These measures have not proved successful. If they produce within the sac simple coagulation, that is, either clots of blood or loose masses of fibrin, they not only fail to effect a cure, but the patient is exposed to the dangers incident to embolism.

[1] *Vide* paper by Dr. Bowditch, Boston Medical and Surgical Journal, 1866.

SECTION THIRD.

DISEASES AFFECTING THE DIGESTIVE SYSTEM.

CHAPTER I.

Introductory Remarks. Sporadic Dysentery—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Epidemic Dysentery. Chronic Dysentery. Inflammation of the Cæcum. Perforation. Fecal Abscess. Painful Tumor near the Cæcum.

THE important organs composing the digestive system are, the mouth with the parotid, submaxillary, and sublingual glands, the pharynx and œsophagus, the stomach and duodenum, the small and large intestine with the mesenteric glands, and the solid abdominal viscera, viz., the liver, pancreas, and spleen. Affections of the two outlets of the alimentary canal, viz., the mouth, pharynx, and œsophagus, with the appended glands, and the rectum and anus, properly belong to the department of surgery, being either open to view or accessible by manual exploration, and often requiring surgical operations. These affections, for the most part, will not be considered in this work. This section will, therefore, be devoted mainly to the diseases affecting the hollow viscera and the solid organs within the abdomen. The affections of the digestive system, as of other anatomical systems, consist of, *first*, inflammations; *second*, structural lesions; and, *third*, functional disorders. The inflammatory affections of the hollow viscera will be first considered. Inflammation affecting these viscera may be seated in the mucous membrane lining the alimentary canal, or in the investing serous membrane, the peritoneum. Inflammation seated in the mucous membrane is generally limited to a certain section of the alimentary canal, viz., the portion lining either the stomach and duodenum, the small intestine, exclusive of the duodenum, or more or less of the large intestine. This rule will also be found to apply to functional disorders, that is, the sections just named are apt to be disordered separately. Inflammation affecting these sections gives rise to separate diseases. I shall proceed to consider inflammation of the large intestine, constituting the affection commonly known as dysentery. Inflammation, in this situation, may be either acute, subacute, or chronic. Chronic dysentery will claim consideration under a distinct head. A capital distinction relates to dysentery occurring as a sporadic and as an epidemic affection. Sporadic and epidemic dysentery will claim separate consideration.

Sporadic Dysentery.

The term dysentery has long been in use to designate inflammation of the large intestine, attended with mucous and bloody dejections. As a name for the disease, the term is not very distinctive, its etymology

simply expressing intestinal difficulty; but it is not easy to substitute a term conformable to the nomenclature of inflammatory affections, since there is no anatomical name for the large intestine as a whole. The term *colonitis*, or *colitis*, is sometimes used in the place of dysentery, but this implies that the inflammation is limited to the colon, whereas the rectum is generally, if not always, involved, and, in fact, in some cases of dysentery the affection may not extend above the rectum. The term dysentery has the recommendation of not expressing anything erroneous or doubtful in regard to the pathological character of the disease. Sporadic dysentery is presented in practice as an acute and a subacute affection; that is, the local and general symptoms frequently denote more or less gravity of disease, compelling the patient to keep the bed, and in some cases it is an extremely mild and almost trivial affection. Different cases of the sporadic form present every gradation as regards severity, and there are few diseases in the nosology which offer a wider contrast than the mildest cases of sporadic, and the gravest cases of epidemic dysentery.

Anatomical Characters.—In subacute or mild cases, the inflammation has but little intensity, and may be limited in extent, being confined perhaps to the rectum. As in these cases the disease involves no danger, the opportunity of inspecting the parts after death is not offered. The mildness of the symptoms and the short career of the disease suffice to show that ulcerations or other lesions of importance do not take place in these cases. In acute or severe cases, the inflammation is not only more intense, but more extensive, involving, not only the rectum, but the greater part or the whole of the colon. These cases are liable to end fatally, and the affected membrane is found, on examination after death, to be reddened from active congestion, swollen, softened, pulpy, presenting, in different cases, ecchymoses, excoriations from desquamation of the epithelium, abrasion and ulcerations, in greater or less number, the latter being sometimes small and sometimes of considerable size. The ulcers may or may not be seated in the intestinal glands and follicles. The redness and swelling are frequently not uniform over the extent of intestine affected, but are either limited to, or more marked in certain portions, more especially the projecting folds of the membrane. Small vesicles are sometimes observed. The swelling of the membrane is due, in part, to submucous infiltration, and the latter is sometimes so great, at certain points, as to give rise to protuberances resembling warty growths or fungoid excrescences. These protuberances may be more or less numerous, and sometimes coalescing give to the surface a mammelonated aspect. Patches of exuded fibrin are frequently adherent to the inflamed membrane, presenting a greenish or brownish color. The intestine contains more or less morbid matter corresponding to the dejections during life, consisting of mucus, pus, fibrinous flakes, desquamated epithelium, and sero-sanguinolent liquid. The intestine may present a dark and almost black appearance from congestion; but sphacelation, beyond the circumscribed sloughing which precedes ulcerations, is rare. As a rule, the appearances denote progressively a greater amount of disease in passing from the upper part of the large intestine downward to the anus, the greatest amount being at the rectum and sigmoid flexure. There has been much discussion whether the morbid appearances in dysentery denote ordinary inflammation varying in different cases in intensity, or whether they are due to a peculiar morbid process; also, whether the intestinal glands and follicles are generally and primarily involved. It does not

fall within the scope of this work to consider the morbid anatomy with reference to these points of inquiry.

The mesenteric glands are sometimes found to be considerably enlarged, and in some instances to contain pus.

The cicatrization of ulcers in some cases leads to stricture of the intestine.

Clinical History.—The disease is generally preceded by an ordinary diarrhœa; that is, more or less frequent dejections of a feculent character. Of thirty-three recorded cases which I have analyzed with reference to this point, these dejections preceded the characteristic dysenteric evacuations in thirty. The latter appeared after the former had existed for a period varying from twenty-four hours to seven days.[1] With this prodromic diarrhœa there are colic pains, the appetite is impaired, and there is a general feeling of malaise. A pronounced chill rarely occurs, and even chilly sensations are not common.

The development of the disease is denoted by characteristic evacuations consisting of mucus, with which more or less blood is usually commingled. The quantity passed at each act of defecation is generally small, but the act is frequently repeated, slight evacuations often taking place every hour or two, and sometimes after intervals of a few moments only. The quantity of mucus expelled in some cases is abundant, and forms a jelly-like mass, not unlike a collection of the rusty sputa of pneumonitis. The popular term applied to the matter of these evacuations is slime, and by those who are familiar with the preparation of intestines for sausages, they are often compared to the "scrapings of hogs' guts." Rarely in sporadic, but not infrequently in epidemic dysentery, the evacuations contain fibrinous laminæ or flakes in greater or less quantity. A sero-sanguinolent liquid, either small in quantity or abundant, also occurs occasionally in sporadic, but much oftener in cases of epidemic dysentery. The latter has been compared to water in which meat has been washed, and was called by the older writers *lotura carnium*. Most of the evacuations are exclusively dysenteric, that is, consisting of mucus, epithelium, lymph, and blood, but with some of the evacuations fecal matter is discharged. Frequently this presents a green color. If the characteristic dejections be filtered, the liquid which is obtained is found to be notably rich in albumen, the greater part solidifying on the addition of nitric acid. Occasionally round hardened lumps of feces are expelled; these are called *scybala*. The amount of morbid matter evacuated, together with the absence of fecal matter, constitutes, measurably, a criterion of the extent of intestinal surface affected. In the course of the disease the evacuations may contain more or less purulent matter, but this belongs more especially to chronic dysentery. In lieu of the fecal odor, they frequently emit a putrid or cadaveric fetor.

The inflammation of the rectum occasions a sensation as if this portion of the bowel were filled, and leads to the frequent desire to defecate, with as much straining as the soreness of the parts will allow. This desire to strain ineffectually is called *tenesmus*. Sometimes the straining efforts produce prolapsus of the intestine. The evacuations are frequently preceded by griping or colic pains, which have been called *tormina*. The tormina and tenesmus are not proportionate to the gravity of the disease; they are sometimes wanting in fatal cases, and are prominent symptoms in some

[1] Clinical Report on Dysentery, based on an analysis of forty-nine cases, by the author. 1853.

mild cases. They are, however, the chief sources of suffering. Tenderness on pressure is in some cases more or less marked over the descending colon, and sometimes over the whole tract of the large intestine. It is rarely great, and not infrequently wanting. Meteorism or tympanitic distension is rarely present; the abdomen is usually depressed. Strangury and retention of urine are occasional symptoms, and, in the female, leucorrhœa may be produced.

The pulse, in the majority of cases, is but little, and sometimes not at all, accelerated. Exceptionally, high febrile movement exists; this is in robust persons, the inflammation being more intense and diffused than usual. Great frequency of the pulse always denotes gravity and danger, but the converse does not hold good; in some fatal cases the pulse is never much accelerated. The skin is generally either cool or moderately hot, but, exceptionally, with high febrile movement, there is much heat of the surface. The tongue may be frosted, or more or less coated, or it may present a natural appearance. During the course of the disease, the appetite is more or less diminished, or lost. Thirst is usually present, and is sometimes urgent. Vomiting occasionally occurs, and may be prominent as a symptom, the matter vomited being of a greenish color. The intellect is unaffected as a rule, delirium occurring with great infrequency in cases which end in recovery, but occasionally, in cases which prove fatal, toward the close of life. The loss of strength varies greatly in different cases according to the intensity and extent of the local affection, depending, also, on the condition of the patient when attacked.

The duration of the disease, from the date of the attack to convalescence, varies from four to twenty-one days. These figures represent the minimum and maximum duration in thirty recorded cases.

Pathological Character.—Our knowledge of the pathology of sporadic dysentery embraces only the intestinal affection, the local and general phenomena which make up the clinical history being symptomatic of this affection. The disease is a spontaneous inflammation of the large intestine, using the term spontaneous in the sense already defined; it is altogether probable that the inflammation is developed as a result, or a local expression, of a prior internal morbid condition of which we have at present no knowledge. This view of the pathological character is consistent with what will be presented under the head of causation. The view, however, is by no means peculiar to this disease, but is applicable to most of the so-called spontaneous local affections.

The question arises in this connection—Is there more than one species of sporadic dysentery? Writers have described different kinds of the disease, which they have distinguished as typhous, bilious, intermittent, and remittent, rheumatic, febrile and non-febrile, etc. These terms denote either variations in the phenomena of the disease or the coexistence of other diseases. Dysentery may occur as a complication of the continued and periodical fevers. So rheumatism and dysentery are occasionally associated. These combinations are important in their practical relations, but it does not follow that the disease, under these circumstances, is specifically different from its ordinary form. Variations as regards febrile movement, supposed disorder of the liver, etc., do not affect the special character of the disease. Paralysis affecting certain muscles, especially the muscles of the lower limbs (paraplegia), has been observed, in some cases, to either accompany or follow dysentery; and different theories have been proposed to explain the pathological connection between the paralytic and the dysenteric affection. The truth is, the

affections are so rarely connected, that perhaps the most rational conclusion is, their association is a mere coincidence. At all events, paralysis, either as a complication or sequel, does not occur often enough to show any intrinsic tendency thereto in dysentery.

Causation.—No age is exempt from liability to this disease, but, in the majority of cases, the patients are adults and under thirty-five. This was true of 30 out of 44 cases analyzed with reference to this point. A larger number of males than females are attacked, but the preponderance is not sufficient to show that a marked predisposition relates to sex. The causation has a very obvious relation to climate. The disease is vastly more frequent, in the sporadic as well as epidemic form, in tropical than in cold and temperate climates. The causation has also a striking relation to season. Of forty-four cases which I recorded during fourteen years, all save one case occurred in July, August, September, and October. The constitution and previous health were good in one-half of the cases which I have analyzed, and in the remaining half there was no uniformity in character as regards the antecedent affections or disordered health.

Writers have been accustomed to state that the disease may be produced by various obvious causes, such as atmospherical changes, excesses in eating and drinking, indulgence in acid, unripe fruits, crude vegetables, etc. But in the majority of cases, it is not easy to trace its origin to these causes, nor to any obvious cause. This renders it probable that a special cause is involved in sporadic, as well as in epidemic, dysentery. The limitation of the occurrence of the disease to the summer and autumnal season, and its more frequent occurrence in tropical climates, point to this conclusion, and to the agency of a high temperature in the evolution of the special cause. Various circumstances stand in a causative relation to the disease in an epidemic form, which may also be more or less frequently involved in its production when it is sporadic. These causative circumstances will be noticed in treating of epidemic dysentery. There are no grounds for considering sporadic dysentery as contagious.

Diagnosis.—The diagnosis of dysentery involves no difficulty. The characteristic evacuations are pathognomonic. It is to be discriminated from cases of bloody evacuations and irritation of the rectum incidental to hæmorrhoids, of intestinal hemorrhage or melæna, and of the discharge of pus from an abscess opening into the intestine. The points of contrast with dysentery which these cases offer are sufficiently apparent.

Prognosis.—Sporadic dysentery, in temperate climates, intrinsically tends to recovery. It is a distressing disease, but attended with very little danger to life. A fatal result is due either to an unusual intensity and extent of the local affection, or to an inability of the system to resist the disease, from feebleness of the constitution, or to some coexisting affection. The prognosis in tropical climates is undoubtedly less favorable. The recovery from the disease in temperate climates is almost always complete; that is, it rarely eventuates in chronic dysentery. Nor does it leave a predisposition to any other disease. In tropical climates, abscess of the liver is not an infrequent sequel. This very rarely, if ever, follows in temperate climates. Its occurrence is attributed either to the absorption of septic matter from the intestinal canal, or to the detritus of thrombi formed in the veins of the intestine. So far as my experience goes, immediate relapses are not apt to take place, and the occurrence of the disease does not induce a greater liability to its recurrence at a subsequent period.

With reference to the latter point, my analysis of cases, although the number was not large, developed an interesting result. Of all the cases occurring during fourteen years, in not a single instance was the disease known to recur. And in sixteen of these cases the patients were under observation after recovery during periods varying from one year to thirteen years. This result was the more striking from the fact that the patients for several years were within the sphere of an epidemic influence, which, in some instances, affected other members of the same families.

TREATMENT.—In the great majority of cases, sporadic dysentery would doubtless end in recovery without medicinal treatment. But there is reason to believe that the disease is sometimes arrested, that its duration may be frequently abridged, and the distressing symptoms may be greatly relieved, by judicious therapeutical measures.

It is desirable that, as early as possible, the fecal contents of the large intestine should be effectually removed, in order to prevent their continued passage over the inflamed surface, and to secure, so far as may be, that important end in the treatment of all inflammations, viz., quietude of the inflamed part. It would seem that nature endeavors to relieve the bowels of their contents by the diarrhœa which precedes the dysenteric evacuations. The first point in entering on the treatment is to ascertain if the bowels have been spontaneously relieved. With reference to this point, the size and character of the stools are to be ascertained, and the abdomen examined by palpation. In general, it is advisable to render the effort of nature more complete by giving an effective purgative. Castor-oil has been in much repute as an appropriate remedy, but, aside from the objection on the score of the disgust which many persons have for this remedy, the saline cathartics are to be preferred. The sulphate of magnesia or soda, the Rochelle salts, or the citrate of magnesia, may be employed. The saline selected should be given in sufficient doses to produce promptly abundant dejections, and it is then to be discontinued. It will sometimes happen that after free purgation, the dysenteric evacuations do not return, and recovery at once ensues. This abortive effect takes place only in some cases in which the inflammation is not intense, and is limited to the lower part of the intestine. Notable diminution of the frequency of the dysenteric evacuations, and relief of the tormina and the tenesmus, not infrequently follow the operation of the saline purgative. This treatment may be pursued except in cases in which it is contra-indicated by great feebleness of the constitution of the patient.

After purgation, opium, in some form, is the remedy to be most relied upon. A full dose of opium administered by enema, or as a suppository, will sometimes succeed in arresting the disease. It often mitigates the severity of the disease and affords marked relief. Administered by the rectum, however, it is not always retained, and then reliance must be had upon its administration *per orem*. It may be given in full doses repeated every four, six, or eight hours, or in smaller doses repeated at shorter intervals. As regards the form of opium selected, I believe this is chiefly important in respect of the preference or peculiarity of the patient. I have seen the opium in gum or powder, the various liquid preparations, and the salts of morphia equally effectual. The form found to be preferable is to be continued during the progress of the disease, the doses being regulated by the frequency of the evacuations and the suffering. Experience in each case is to be the guide as to the mode of administration. Generally the administration by the mouth and rectum alternately is advisable. The opiate remedies are to be gradually diminished as the dysenteric

evacuations become less frequent and the suffering from tormina and tenesmus is less. After two or three days, if the disease continue, the saline purgative may be repeated if not contra-indicated by the feebleness of the patient, and afterwards the use of opium resumed. Skoda has suggested that opium in dysentery, and in certain cases of diarrhœa, is efficacious by keeping the sphincter ani in a state of contraction, and by causing permanent contraction of the small intestine so that the contents of the latter are not propelled far enough to induce the irritation which causes their expulsion; and the contents thus retained in the small intestine may be considerably diminished by absorption.

In this plan of treatment the reliance is upon free purgation and opium. The chief reliance, I believe, should be upon these measures; but other measures may be conjoined. The subnitrate or the subcarbonate of bismuth in scruple or half drachm doses, the acetate of lead, the sulphate of copper, gallic acid, and the various vegetable astringents, such as rhatania, kino, catechu, hæmatoxylon, etc., are useful as adjuvants. These are to be relied upon, to the exclusion of opium, in those cases only in which, from a constitutional peculiarity, the latter produces unpleasant effects sufficient to preclude its employment. It is undoubtedly true that some persons are affected so unpleasantly by opium that its use is, if possible, to be avoided; but it is often the case that it is well borne in this and some other diseases, although it may not be in trivial affections. Certain preparations may be well borne, although others occasion unpleasant effects. An aqueous solution or extract is frequently taken without difficulty by those who cannot comfortably take other preparations. Codeia sometimes answers a good purpose as a substitute for the preparations of opium and morphia.

Ipecacuanha has been considered a valuable remedy in dysentery. Some have attributed to it a special curative influence, and have advocated its employment in as large doses as can be borne. Dr. Maclean, professor of clinical and military medicine in the army medical school, Netley, states that the system of treating acute dysentery, now generally followed in India, is as follows: Thirty drops of the tincture of opium may be at first given, but this may be sometimes omitted and the ipecacuanha given at once. If the opiate be given, in half an hour it is to be followed by from 25 to 30 grs. of ipecacuanha. The latter remedy should be given in as small a quantity of fluid as possible, and a little syrup of orange-peel covers the taste of the medicine. The patient, after this dose, should keep perfectly quiet and abstain from fluid for, at least, three hours. With these precautions, nausea and vomiting are rarely troublesome. After eight or ten hours, the ipecacuanha may be repeated in a reduced dose, observing the same precautions. Dr. Maclean states that the effects of one or two doses of the ipecacuanha, given in this manner, are often surprising; "the tormina and tenesmus subside, the motions quickly become feculent, blood and slime disappear, and often, after profuse action of the skin, the patient falls into a tranquil sleep and awakens refreshed."[1] If required, the treatment is to be continued for several days, the remedy being given in diminished doses, with intervals sufficient to allow mild nourishment to be taken. He cites statistics showing the mortality in India, under the use of ipecacuanha, to be 28.87 in a thousand; whereas, under the old system the mortality was 88.2 in a thousand. It is to be borne in mind, however, that the old system of treatment embraced bloodletting and the free use of mercury. I have resorted to this

[1] *Vide* article in "A System of Medicine," edited by Reynolds, vol. i. 1866.

plan of treatment in a considerable number of cases at Bellevue Hospital, but without a very satisfactory degree of success. In a small proportion of cases the disease was either arrested or favorably modified by it; but in the majority of cases it had no apparent influence on the disease.

Mercury has been, heretofore, much relied upon in the treatment of this disease, given in either large doses, united with opium in order to prevent a cathartic effect, or in small doses repeated at short intervals. This remedy has been thought to be useful in dysentery, as in all inflammations, by reason of a supposed antiphlogistic influence, but, in addition, a special efficacy has been attributed to it from its supposed action on the liver. Deficient hepatic secretion and consequent portal congestion have been regarded as important elements in the pathology of dysentery, and mercury has been looked upon as a remedy having reference specially to these elements. The pathological view just stated, however, is purely conjectural, and clinical observation fails to furnish evidence of any special curative influence to be derived from mercury. The recovery, when treated with mercury, is, of course, no proof of its value in any disease which, like sporadic dysentery, tends intrinsically to recovery. The duration of the disease, the relief of the symptoms, the rapidity of convalescence, and the subsequent condition of health, are the points to be considered in estimating the influence of remedies in this disease. With reference to these points, a fair estimate of the effects of mercury, especially when pushed to ptyalism, it is believed will lead to its rejection as a remedy for dysentery; and, indeed, it has already, in a great measure, in this country, fallen into disuse.

During the early part of the disease, the diet should be restricted to a small quantity of the blandest articles of food. It is an object throughout the disease to keep the patient on a diet which will leave but little residuary matter after digestion to pass into the large intestine; in other words, a diet as purely nutritious as possible. After the first few days, however, it is important to provide for proper support of the system by nutritive supplies, and for this purpose milk and animal broths are best suited. If the symptoms denote failure of the vital powers, concentrated nourishment and alcoholic stimulants are to be given freely, as in all diseases which destroy life by asthenia. Tonic remedies may be given with advantage during convalescence.

Patients should be instructed to refrain as much as possible from repeated acts of defecation and straining efforts. They will be induced to do so if it be explained to them that the sensation of fulness of the rectum is delusive, being dependent on the inflamed condition of the membrane. Cold applications to the anus sometimes relieve the tenesmus. A piece of ice may be wrapped in cloth and applied frequently in this situation. Enemas of cold water are often grateful. Relief, in some cases, is afforded by injecting astringent liquids. The nitrate of silver, a solution of tannin, acetate of lead, or the sulphate of zinc, may be thus used. Dr. Gairdner recommends highly large emollient injections, each containing from five to ten drops of creasote. Dr. Thomas F. Cock, of this city, has found that notable relief of the tenesmus is afforded by the introduction within the rectum of the vapor of chloroform. It is introduced by pouring a little chloroform (about 20 drops) upon a piece of sponge, which is placed in a common syringe, the tube passed into the rectum and kept there until enough of the vapor has been introduced to afford relief. It is not necessary to use any means of forcing the vapor into the rectum, but the vaporization is rendered more rapid by warming the syringe. Care is to be taken that the chloroform does not come in contact with the anus.

Fomentations and mild revulsive applications over the abdomen are useful as palliatives in proportion to the amount of tormina and abdominal tenderness.

EPIDEMIC DYSENTERY.

Epidemic dysentery is essentially the same disease as sporadic dysentery. Certain events occur much oftener in the former than in the latter, yet there is nothing pertaining to the epidemic which is not occasionally seen in the sporadic form of the disease. Epidemic dysentery is often very fatal, yet, in the epidemics attended with the largest fatality, cases occur which are as mild as the mildest sporadic cases, and, on the other hand, occasionally in sporadic cases life is quickly destroyed. Like other diseases which prevail epidemically, this differs greatly at different times and places as regards gravity, and at certain times and places it presents features which it does not present at other times and places. The differences between different epidemics of this disease are in a measure to be explained by the coexistence of other diseases, and by the conjoint operation of morbific causes not standing in a special relation to the production of this affection. In treating of epidemic dysentery, the main object will be to point out the circumstances in which it is apt to differ from sporadic dysentery.

With respect to the anatomical characters, they are essentially the same as in cases of sporadic dysentery. In fatal cases of either form, the varied appearances which have been stated may be found. Extensive and disorganizing changes oftener occur in epidemic dysentery. As a rule, in the latter the inflammation extends over a larger portion of the large intestine, and it sometimes extends into the ileum. Ulcerations and diphtheritic exudation are much more apt to occur in epidemic dysentery. Perforation of the intestine is sometimes a result of ulceration, giving rise to peritonitis. Perforation of the cæcum may take place in this disease, leading to abscess in the areolar tissue beneath the peritoneum, or fecal abscess. Perforation of the rectum and fecal abscess in that situation have been known to occur.

The clinical history of epidemic differs from that of sporadic dysentery according to differences as regards the extent and severity of the local affection, and also according to various morbid conditions due to the action of accessory causes, the latter oftener co-operating in epidemic than in sporadic cases. Severe cases of epidemic dysentery are characterized by the occurrence of sero-sanguinolent dejections, the *lotura carnium* of the older writers, containing usually flakes of lymph in more or less abundance, and holding in solution albumen in abundance. Hence, epidemics of dysentery are popularly known as *bloody flux*. Dejections of this character always denote gravity of disease. Tormina and tenesmus may be less prominent as symptoms in severe cases of epidemic than in most cases of sporadic dysentery. In some fatal cases these symptoms are entirely wanting. Tenderness over the tract of the colon may, or may not, be marked. The local symptoms in some cases of epidemic dysentery are comparatively slight, and in general, so far as my observation goes, patients suffer far less in fatal cases than in sporadic cases wholly devoid of danger.

The differences, as regards the general symptoms, in different epidemics and different cases, are marked. Severe cases are characterized by prostration, feebleness of the circulation, coldness of the surface, in short, by symptoms denoting adynamia. The pulse may become frequent, small,

soft, vibratory but compressible, or it may be small, weak, thready, with but little, and sometimes not any, increase of frequency. These characters of the pulse, denoting feebleness of the action of the heart, together with other adynamic symptoms, are developed in some cases early in the disease, without having been preceded by active febrile movement, but in other cases the pulse for a time is full and strong, the skin hot, the adynamia succeeding these symptoms of high symptomatic fever. In fatal cases, a condition analogous to the stage of collapse in epidemic cholera may precede, for a variable period, the termination of the disease. In this condition the pulse is scarcely appreciable, or it is extinct, the surface is cold and either dry or bathed in perspiration, the teeth are sometimes covered with sordes, the quantity of urine is greatly diminished, cramps of the muscles of the lower extremities sometimes occur, and this collapsed condition may exist for one, two, or three days before death. The mode of dying is by slow asthenia.

The intellect generally remains intact, or slight mental aberration only occurs in the latter part of life. But some cases are characterized by delirium. The patient talks incoherently under the influence of transient delusions; he may attempt to get out of bed, and require to be restrained. In a case which came under my observation some years ago, the delirium was of a boisterous, mirthful character, the patient singing snatches of humorous songs, shouting, and attempting to get out of bed, after the pulse had become extinct, and the surface of the body was cold like that of a cadaver. In this case, the manifestations of delirium were so painfully incongruous that the patient was kept sufficiently under the influence of chloroform to repress them for several hours before his death.

The delirium and other symptoms, in some cases, are analogous to those belonging to typhus and typhoid fever. The typhoid state may exist in cases of this disease as of various other affections. But is to be borne in mind that dysentery sometimes occurs as a local complication of typhus and typhoid fever. Certain epidemics of these fevers are characterized by the occurrence of this complication. The distinction between dysentery with typhoid symptoms, or typhoid dysentery, and typhus or typhoid fever with a dysenteric affection developed secondarily, is the same as between typhoid pneumonitis and typhus or typhoid fever complicated with pneumonitis. The symptoms of scorbutus are associated with those of dysentery when, as is sometimes the case, the latter prevails among persons who are suffering from scorbutic deterioration of the blood. So, in districts where periodical fevers prevail, epidemics of dysentery may be characterized by periodicity as regards febrile movement, etc., due to the union of dysentery with intermittent or remittent fever, or the conjoined operation of the special cause producing the latter.

The duration of the disease in cases of epidemic dysentery is very variable. In malignant epidemics, the disease sometimes runs very rapidly to a fatal issue, the collapsed condition occurring perhaps in the course of a few hours. On the other hand, cases may be protracted to the third and fourth week before either convalescence or death takes place. As already stated, different epidemics differ widely as regards the severity of the disease. In some epidemics, the majority of cases are mild and the rate of mortality is very small; but in other epidemics the proportion of deaths is very large. The latter are justly distinguished as malignant. There are few epidemics more to be dreaded than those of malignant dysentery. They occur much oftener in tropical than in temperate climates, but there is no part of the world exempt from their occasional occurrence. It is one of the scourges of camps in time of war, especially if, to causes operating

particularly on armies, tropical influences be added. It prevailed to a very great extent in the late civil contest in this country, among the national and the insurgent forces, especially in the Southern States, and it was often associated with phenomena referable to malaria.

The causation of epidemic dysentery doubtless always involves a special cause which is undoubtedly derived from without the body, or external. The special cause is probably essentially the same in epidemic as in sporadic dysentery, differing, at different times and places, either in quantity or in morbific intensity. The various agencies which may appear to give rise to the disease, such as the exposure to atmospheric vicissitudes, fatigue, and other hardships incident to army life, insufficiency of diet, over-crowding, marsh miasmata, etc., probably act only as co-operating causes, rendering the system more susceptible to the dysenteric poison and giving rise to other morbid phenomena than those which the special cause would alone produce. Epidemics would probably not often occur were it not for the operation of accessory causes; hence the rationale of their occurrence in camps, in prisons, and in situations where numbers are exposed to hygienic influences favorable for the development of any disease. With respect to the source of the special cause of dysentery, or the conditions under which it is generated and diffused, we have at present no positive knowledge. The contagiousness of epidemic dysentery has been a much mooted question. Without entering into any discussion of this question, I shall content myself with saying that this is probably one of a group of diseases, the evidence of the communicability of which rests mainly on the successive occurrence of a greater or less number of cases among members of one household, or persons who, from proximity of residence, are brought into contact with each other; and the diffusion of the disease, under these circumstances, may be satisfactorily accounted for by the fact that the persons attacked are alike exposed to the special cause, together with the same co-operating causes. It is, however, proper to state that some distinguished authors suppose that the intestinal excreta contain a virus by means of which the disease may be communicated.[1]

The opinions of different writers and practitioners concerning the treatment of dysentery, especially as an epidemic, show great diversity, and there is abundant testimony of the success of measures quite opposite in character. The fact just stated shows, either that the recoveries were due mainly to an intrinsic tendency of the disease, or that the disease is presented at different times and places under different pathological phases, and the measures of treatment require to be correspondingly varied. Both explanations are doubtless measurably applicable. Sporadic dysentery, as a rule, and not unfrequently epidemic dysentery, tend intrinsically to recovery. Recovery, under these circumstances, takes place, whatever be the treatment, provided it be not destructive. The success of treatment in such cases is shown by the short duration of the disease, its diminished severity, etc. On the other hand, in a certain proportion of cases of epidemic dysentery, the disease must, of necessity, end fatally. The extent of mucous surface affected, the loss of fluids by hemorrhage and transudation, and the destructive lesions which take place, preclude recovery under any treatment. But it is also true that the different features which the disease assumes in different epidemics, and the various morbid conditions with which it may be associated, must influence, more or less, therapeutical measures.

Purgatives, especially of the saline class, may be as appropriate in epi-

[1] *Vide* Niemeyer, *op. cit.*

demic as in sparodic dysentery; but they should be given cautiously or omitted if sero-sanguinolent dejections occur or if the symptoms denote much tendency to adynamia. It is immensely desirable to arrest or moderate the dejections just named, for these doubtless conduce to the condition of collapse into which patients are apt to fall. For this purpose, opium is to be given in as large doses as are required or as are well borne, in conjunction with astringent remedies, such as gallic acid, acetate of lead, the persulphate or pernitrate of iron, rhatania, etc. I believe the main reliance should be placed on opium, in some form, in these cases, other remedies being considered as auxiliary. The latter, therefore, are not to be employed as substitutes for opium except in cases in which, from a constitutional peculiarity, this remedy, in any form, produces such distressing effects as to preclude its use. It should not be decided that opium cannot be tolerated on the assertion of the patient, but only after a fair trial.

In this disease, as in some others, there is frequently a wonderful tolerance of opium, a tolerance not to be explained by the antagonizing influence of pain, since it is manifested in cases in which pain is not a prominent symptom. Christison, in stating this fact, adds that he has known from 24 to 30 grains of the gum of opium to be taken in the course of 24 hours. I have given 2 grains hourly, in the case of a female affected with dysentery characterized by abundant sero-sanguinolent dejections for the space of a week, and without, at any time, symptoms denoting narcotism. I have met with a case exemplifying a still greater tolerance of this remedy. In this case, the patient not being habituated to the use of opium before his illness, the quantity of the sulphate of morphia, given hourly, was gradually increased to one grain, making 24 grains in the 24 hours, and this quantity was given for several consecutive days without any narcotism. Opium is not to be given as a matter of course in doses approaching these, but it is to be given with a view to the desired end, viz., the arrest of the sero-sanguinolent dejections; and if this effect be not obtained, the doses are to be increased to the amount which will be borne without narcotism, be the amount never so large. It is hardly necessary to say that, in increasing the dose, the condition of the patient is to be carefully watched; attention is to be directed to the pupils, and to the number of respirations, as well as to the soporific state, in order to avoid a cumulation which may result, unexpectedly, in narcotism. The quantity of opium which may with prudence and propriety be given in dysentery, will vary greatly according to the varying tolerance in different cases.

In proportion as the symptoms denote adynamia, or, in other words, a tendency to death by asthenia, the powers of life are to be supported by alcoholic stimulants and nourishment. The general principles which should govern the employment of supporting measures are the same as in other affections which, in like manner, tend to destroy life by exhaustion. Alcoholic stimulants are sometimes tolerated in large quantity in severe cases of this disease. I have known over 40 ounces of brandy to be taken in 24 hours by a patient who, in health, was not accustomed to the use of ardent spirits, and this large quantity produced no excitation of the circulation or nervous system. This patient was apparently saved by the persevering use of stimulants with large doses of the sulphate of morphia. I have repeatedly seen patients recover under the vigorous employment of supporting measures, conjoined with opium in large doses, when, as judged by the symptoms, the condition appeared to be truly desperate. Yet, of the cases properly distinguished as malignant, many must die, despite the faithful employment of the measures on which the chief reliance is to be placed.

Dysentery associated with phenomena denoting the operation of the

special cause of periodical fever, calls for treatment having reference to the latter, in addition to the measures addressed to the dysenteric affection. Quinia is a highly important remedy in these cases. Associated with scorbutus, the dietetic and remedial measures appropriate to this condition are indicated. Occurring as a complication of the continued fevers, it furnishes an additional indication for the supporting measures which these fevers claim irrespective of the dysenteric complication. Coexisting rheumatism calls for the addition of the remedies which are deemed appropriate for this disease.

CHRONIC DYSENTERY.

The term chronic dysentery should be restricted to cases either of subacute and persisting inflammation of the large intestine, or of ulcerative and other lesions resulting from inflammation in this situation. The term, however, is sometimes incorrectly applied to cases of functional diarrhœa, and, on the other hand, the term chronic diarrhœa is often applied to cases of chronic dysentery.

The large intestine is the seat of ulcers in some cases of tuberculosis, the ulcers resulting from a tuberculous affection here; they may also be connected with carcinomatous disease. They have been found in cases of poisoning by a corrosive substance such as the bichloride of mercury, when the small intestine had escaped. They occasionally occur when their occurrence cannot be explained, and they are sometimes found after death when their existence had not been suspected during life.

The affection properly called chronic dysentery very rarely occurs save as a sequel of acute dysentery; recovery from the latter does not take place, but the inflammation becomes chronic, or, more commonly, ulcerations which take place during the acute affection do not cicatrize, but continue for an indefinite period. Acute dysentery, however, very rarely eventuates in the chronic form of the disease in temperate climates, and, hence, chronic dysentery is extremely rare in these climates. It is otherwise in warm climates. Here the chronic often follows the acute affection. Chronic dysentery thus prevails chiefly in tropical countries, or among those who have contracted acute dysentery in these countries. In the Northern States of the Union, the cases observed are, for the most part, imported from the South. Of the soldiers who returned from the war in Mexico, large numbers were affected with this disease; and, recently, during the civil war, cases were very numerous among the troops sent to the northern military hospitals from different points in the insurgent States.

In chronic dysentery, the evacuations, either constantly or more or less frequently, contain morbid products denoting inflammation or ulceration, viz., mucus, patches or flakes of lymph, pus, together with blood. Cases differ much in the frequency and abundance of these constituents of the evacuations. In severe cases, the stools are always loose and thin, the excrementitious contents of the intestine being liquefied by serous transudation; the function of fecation is suspended. In these cases it is to be inferred that the inflammation or lesions extend over the whole, or the greater part, of the large intestine. In other cases, dysenteric discharges occur more or less frequently in alternation with fecal dejections. In these cases, the inflammation or lesions are less diffused. If the evacuations be generally or frequently solid or moulded, the dysenteric evacuations being superadded, the inflammation or lesions are circumscribed and situated near the anus. In these cases, ulcerations may sometimes be seen, if examination be made with the speculum.

Chronic dysentery is one of the most intractable and hopeless of diseases. For a time, if the evacuations be held in check by palliative measures, the appetite and digestion not being greatly impaired, the general aspect and strength may not show much deterioration, but at length the appetite and digestion fail, and the continued irritation and loss of fluids induce progressive emaciation and debility. The duration of the disease embraces usually several months, and sometimes years. If not destroyed by some intercurrent affection, the patient becomes extremely emaciated, reduced almost to a skeleton, the surface is usually dry, cool or cold, the pulse becomes more and more feeble; the mental faculties are weakened, delirium rarely occurring, but the mind, in certain cases, falls into an apathetic state, the patient being indifferent to, and taking but little notice of, persons and things around him. Anorexia becomes complete, and vomiting, in some cases, is a prominent symptom; œdema of the lower limbs sometimes occurs; ulceration of the cornea is an occasional event, and I have known the cornea to be perforated, with loss of the humors of both eyes; the mode in which a fatal termination takes place is generally typical of dying by slow asthenia.

The observations of Prof. A. Clark, at Bellevue Hospital, in the winter of 1862–63, when this hospital was thrown open to sick soldiers from the peninsular campaign in Virginia, go to show the frequent occurrence of disease of the kidneys in cases of chronic dysentery. In seventeen cases reported by the late Dr. Henry W. Cooke, house physician,[1] in which autopsies were made under the direction of Prof. Clark, in all the kidneys were found to be more or less diseased. They were moderately increased in weight, the secreting or cortical portion lighter in color than natural, and having a granular appearance. On microscopical examination, the *tubuli uriniferi* were found filled with granules and detached epithelium. In these and numerous other cases, the urine, examined during life, was found to contain casts of the uriniferous tubes, but no albumen. It remains to be ascertained whether these evidences of renal disease were peculiar to this group of cases of chronic dysentery, or whether they are to be found in cases of the disease occurring at all times and places; and, with respect to the cases in which the kidneys become affected, it is an interesting question, how far the renal affection contributes to the symptomatic phenomena of the disease. Uræmic poisoning was not evidenced, in any of the cases observed by Prof. Clark and others, by convulsions or coma, perhaps because the excessive accummulation of urea in the blood was prevented by the abundant draining away of serum through the intestinal canal. The mental apathy, anorexia, vomiting, and the occasional œdema, may be fairly attributed, in part at least, to diminished elimination of urea by the kidneys.

The diagnosis of chronic dysentery is not altogether easy. The disease is to be discriminated from functional diarrhœa, and this is not always readily done. The presence of pus, lymph, mucus, and blood at times, if not frequently or constantly, is the important point in the differential diagnosis. It is also to be discriminated from ulceration of the large intestine due to tuberculosis, or carcinoma, or other causes. Tuberculosis may be excluded if the lungs be free from the deposit of tubercle. In carcinomatous disease, frequently a tumor is to be felt through the abdominal walls, or if seated in the rectum it is accessible to examination by means of the touch and speculum. The fact that chronic, is, in the great majority of cases, preceded by acute dysentery, is highly important in the diagnosis.

[1] American Medical Times, Feb. 20, 1863.

We may conclude at once that the disease is chronic dysentery if it have followed the acute disease, and the latter fact may generally be without difficulty ascertained, owing to the well-marked diagnostic symptoms of acute dysentery. In temperate climates the affections with which chronic dysentery is liable to be confounded are most likely to exist in cases of doubt, owing to the great infrequency of the latter.

The treatment of chronic dysentery relates, *first*, to the local affection. Remedies to allay irritation and to promote the healing of ulcerations are indicated. But, unhappily, in the great majority of cases, there is very little probability that a cure will be effected, and all that can be hoped for from judicious treatment are palliation of symptoms and prolongation of life.

Certain remedies have been employed with a view to their direct action upon the affected portions of the intestine. The nitrate of silver is one of these; but it is absurd to suppose that this remedy, given as largely as prudence will allow, passes through the stomach and small intestines unchanged. Whatever benefit may be derived from it, therefore, is not to be explained on the ground of its topical application to the diseased surface. The balsamic medicines, particularly the balsam of copaiba, have been given for the same purpose, and with more reason; but clinical observation shows not much benefit to be derived from them. The subnitrate or carbonate of bismuth may be included among the remedies supposed to act by coming in contact with the affected parts. This remedy is often beneficial as a palliative, the dejections becoming less frequent, with relief of pain, etc., under its use. It should be given in doses of from 20 to 30 grains three or four times daily. Some have recommended much larger doses, and, given almost without limit, it produces no deleterious effects; but probably all the benefit to be derived from it is secured by the doses just stated. Its administration in enemas has been advocated in this disease. The various astringent remedies are to be tried in succession. Of those most likely to be useful, the following may be mentioned: tannic or gallic acid, alumen, rhatania, rubus villosus (blackberry-root), and the persulphate or pernitrate of iron. Dr. Beck, of Cincinnati, recommends, as a valuable remedy in both acute and chronic dysentery, but especially the latter, common resin, given in doses of a scruple or more every four hours.[1] He states, in a letter to the author, that he has used this remedy in his practice, with much success, for the last twelve years. He attributes its efficacy to its local action on the diseased membrane.

In so far as the dejections are controllable by the foregoing remedies, they should be relied upon to the exclusion of opium, because they will interfere less with the appetite and digestion. Opiates, however, will be required, to a greater or less extent, in conjunction with other remedies. So far as practicable they should be administered by the rectum, either in enemas (a salt of morphia, or some liquid preparation, contained in an ounce of mucilage or thin starch-water), or in suppositories. The lower part of the rectum should be examined with the speculum, and appropriate topical applications made if ulcers in this situation be discovered.

The treatment relates, *secondly*, to the system. In relative importance, the general take precedence of the local measures. The surface of the body should be well protected against atmospheric changes. The diet should be nutritious but bland, articles of food being selected which do not leave much indigestible matter to pass into the large intestine. Milk, eggs, and farinaceous food are generally best suited, but in some cases animal food

[1] Cincinnati Medical and Surgical News, edited by J. C. Beck, M.D., July, 1863.

is found to agree. The plan of diet is to be governed by experimental trials. Tonic remedies and alcoholic stimulants are indicated by defective appetite and digestion. Of tonic remedies, quinia, the chalybeate preparations, the mineral acids, and the bitter infusions are generally to be employed in succession. The use of alcoholic stimulants is to be regulated by their effects in individual cases. Moderate out-of-door exercise and mental recreation are important. Change of climate is sometimes effectual when other measures prove unavailing. The experience of the late war has shown the happiest effect of transferring soldiers to northern hospitals in salubrious rural situations.

Inflammation and Perforation of the Cæcum. Fecal Abscess.

Inflammation of the cæcum, the inflammation limited to this portion of the large intestine, constitutes an affection called *typhlitis*, *tuphlo-enteritis*, or *cæcitis*. Acute inflammation confined to the cæcum is not of frequent occurrence. The symptoms are, pain and tenderness within a circumscribed space corresponding to the situation of the cæcum, with vomiting, diarrhœa, and febrile movement. It is liable to be confounded with phlegmonous inflammation connected with disease of the vertebra, renal calculus, circumscribed peritonitis from perforation of the vermiform appendix, and, in the female, inflammation of the right ovary. Peritoneal inflammation, limited to the portion of peritoneum covering the cæcum, may accompany the affection. The pain and tenderness are then more marked, and the cæcum is distended by an accumulation of gas, the peritoneal inflammation producing paralysis of the muscular tunic. The distension sometimes is so great that this portion of the large intestine is distinctly seen and felt through the abdominal walls. Diarrhœa is not uniformly present. Extension of the limbs may occasion pain, as in cases of general peritonitis. The cases which I have seen have terminated in recovery. I have not met with perforation followed by either general peritonitis or fecal abscess in a case of acute inflammation of the cæcum. Subacute or chronic inflammation gives rise to symptoms less distinctive. It may occur, and recovery take place without the development of symptoms denoting an affection of importance; but it becomes a very important affection in certain cases in which it leads to ulceration and perforation of the intestinal coats. If the perforation take place in that portion of the cæcum not invested with the peritoneum, the gaseous and other contents of the intestine, escaping into the areolar tissue, give rise to inflammation which may be either diffused or circumscribed, in the latter case forming an abscess called a fecal abscess. If diffused, the inflammation may extend more or less over the abdominal walls, which become swelled, pitting on pressure as in œdema, with a feeling of crepitation due to the permeation of intestinal gas. If an incision be made, a dark, sanious liquid escapes with gas emitting an intestinal odor. Under these circumstances, a fatal result is inevitable. If, however, the perforation lead to a circumscribed abscess which opens externally, gas and fecal matter, with pus, escape, a fistulous communication with the intestine is established, and this may remain permanently, or it may gradually close and recovery take place. Some years since I met with a medical gentleman who, several years before, had cæcitis with perforation and fecal abscess, resulting in a fistula which had gradually diminished, and, at that time, had nearly closed, intestinal gas having ceased to escape for many months. The recovery, in this case, seemed to be nearly complete. Perforation taking place through the portion of the

intestine invested with the peritoneum, occasions the development of peritonitis. Perforation of the *appendix veriformis*, occurring irrespective of cæcitis, is of not very infrequent occurrence, and will be noticed in treating of peritonitis.

From an analysis of thirty-two cases of fecal abscess, Prof. Roberts Bartholow derives the following conclusions:[1] In the majority of cases, perforating ulcer occurs irrespective of the presence of extraneous bodies; it was attributed to the latter in only six of thirty-two cases. In a large majority of cases, the perforating ulcer selects the posterior part of the gut. Of fourteen cases, in two only did the ulcer involve the portion of the bowel covered by peritoneum. Perforation of the vermiform appendix is not embraced in this statement. If the perforating ulcer be situated in the part covered by peritoneum, general peritonitis, with a fatal termination, is the rule; but circumscribed peritonitis, with adhesions, sometimes occurs, and fecal abscess is the result. Perforation of the appendix usually leads to general peritonitis. Adhesions, however, sometimes occur, perhaps before the perforation takes place, and a fecal abscess, without general peritonitis, may be a result. It is probable that suppurative inflammation of the sub-cæcal connective tissue, irrespective of either perforation or of prior disease of the cæcum, is very infrequent, if indeed it ever occurs. In cases of perforation of a portion of the cæcum not covered by peritoneum, caused by a foreign body, the prognosis is favorable. Recovery takes place in one-half of the cases of perforation of a part not covered by peritoneum, by a perforating ulcer. The prognosis is always unfavorable in cases of perforation of the appendix. As regards diagnosis, fecal abscess is to be discriminated from psoas abscess, abscess with caries of pelvic bones, pelvic cellulitis, abscess in abdominal wall, and disease of the hip-joint. Tympanitic distension and crepitation on pressure due to the presence of intestinal gas are diagnostic points.

A specimen was shown to the New York Pathological Society, by Dr. Krackowitzer, March, 1867, in which the vermiform appendix had become attached to the bladder and perforation had followed, causing a vesico-intestinal fistula. The first evidence of this was the appearance of a lumbricoid worm at the end of the penis, the patient then being eight years of age. Subsequently other worms were discharged, and repeatedly the seeds of fruit. Most of the urine was discharged by the bowels. The fistula for many years gave but little inconvenience. The patient served as a soldier in the late civil war. He was operated upon for stone in the bladder when 28 years of age, and died five days after the operation, the fistula thus having existed for twenty years. A similar case is given by Davaine in his work on Entozoa.

The late James Jackson, of Boston, in his admirable work entitled "Letters to a Young Physician," describes an affection under the name, "a painful tumor near the cæcum." As this name implies, pain is felt in a situation near the cæcum, and a tumor is found in this situation. The pain and tumor are situated on a horizontal line connecting the two anterior superior spinous processes of the ileum, at the point where this line intersects the right margin of the rectus muscle on the right side. The pain is sometimes marked, and felt especially on movements of the body. The tumor is oval, and is quite small. It is not superficial, but is felt on deep pressure through the abdominal wall. Marked tenderness on pressure exists within a circumscribed space over the tumor. In the cases detailed by Dr. Jackson, the pain and tenderness, together with the tumor, slowly

[1] *Vide* American Journal of Medical Sciences, October, 1866.

disappeared under treatment with cathartics, leeches, a blister to the part, and opium to relieve pain. Dr. Jackson confesses his inability to form an opinion as to the precise seat and character of this affection. I will venture the conjecture that it is inflammation of the mucous membrane lining the *appendix vermiformis*, with dilatation, either from the products of inflammation or fecal matter, the inflammation extending, perhaps, in some cases, more or less, over the lining membrane of the cæcum. Several cases presenting the features described by Jackson have fallen under my observation. In none of the cases which I have observed has perforation taken place, and none have ended fatally.

CHAPTER II.

Acute Enteritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Enteritis. Acute Gastritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Gastritis. Duodenitis. Pharyngitis. Parotiditis.

Acute Enteritis.

INFLAMMATION of the mucous membrane of the small intestines is designated *enteritis*. This name, signifying inflammation of the intestine, is conventionally restricted in its application to inflammation of the small intestine. As a rule, inflammation is limited to either the small or large intestine, but as, exceptionally, in cases of epidemic dysentery the inflammation extends from the cæcum into the ileum, so, in some cases of enteritis the inflammation descends into the colon. Are the several portions of the small intestines liable to be inflamed separately; in other words, may ileitis, jejunitis, and duodenitis occur as separate affections? There is ground to suppose that the duodenum may be inflamed by itself, or, at all events, duodenitis has certain pathological relations which render it desirable to consider it as a distinct affection, but it is impossible to distinguish clinically jejunitis and ileitis.

The small intestine is the seat of a highly important local affection, seated in the Peyerian and solitary glands, which is characteristic of typhoid fever. It is also the seat of the deposit of tubercle in a certain proportion of the cases of tuberculosis. Exclusive of these affections, which are elsewhere considered, acute enteritis is a rare form of disease after infantile life. It belongs among the affections to which young children are especially prone. Yet examples are occasionally met with in practice, occurring in the middle-aged and the aged, as well as in the young. Referring the reader to works which treat of the diseases of children for an account of this disease as occurring in infantile life, it will require but a brief consideration.

Anatomical Characters.—As the disease, in itself, rarely proves fatal, the opportunity of inspecting the appearances after death is not often offered. This fact shows that lesions corresponding to those in fatal cases

of dysentery—ulcerations, sloughing, sphacelus—do not occur in enteritis. The mucous membrane is usually more or less reddened; the redness is arborescent, and is best shown by an examination of dried specimens; the membrane is softened and thickened; softening of the submucous tissue from infiltration also occurs, rendering the detachment of the membrane easier than in health; ecchymoses within and beneath the membrane are sometimes observed. The Peyerian and solitary glands remain unaffected. The affected surface is more or less abundantly coated with mucus. The morbid changes are either limited to the ileum or more marked in this portion of the small intestine, and the lower part of the ileum is usually most affected.

Clinical History.—The local symptoms, in cases of acute enteritis, are pain, tenderness over the abdomen on pressure, and diarrhœa, with nausea and vomiting. The pain is not intense, and is of a dull, aching character, with exacerbations in which it resembles the pain of colic. The pain is referred to the umbilical region. The tenderness is not great. Slight pressure is well borne, but deep, firm pressure occasions more or less suffering. The tenderness is over the lower part of the ileum and around the umbilicus. Diarrhœa is generally, if not always, present. It is stated by Habershon that the bowels may remain constipated through the disease, but examples are probably very rare. The stools are more or less frequent, and in character they are loose or watery, and gelatinous from mucus intimately mixed. Tenesmus does not exist unless inflammation of the lower part of the larger intestine be added. The dejections are frequently acrid, producing a painful, burning sensation in their passage. Dysentery is sometimes developed, perhaps, by the irritation caused by the acrid matter contained in the dejections. Nausea and vomiting are excited sympathetically, or, in some cases, perhaps, from an extension of the inflammation to the stomach.

The general symptoms usually do not denote great constitutional disturbance. The febrile movement is slight or moderate. The debility is not great, but sufficient to keep the patient in bed. The intellect is unaffected except in severe cases, when delirium may occur, together with tympanites, hiccough, and symptoms denoting adynamia.

The duration, in favorable cases, is brief, convalescence being declared in a week or ten days.

Pathological Character.—Excluding enteritis occurring in connection with typhoid fever, tuberculosis, and the diseases of infancy, the disease has no special pathological character. It is a simple inflammation of a mucous membrane. It very rarely occurs save as a sporadic disease, in this respect differing from dysentery. It differs also from dysentery in not leading to the destructive lesions of the affected membrane like those which occur especially in the epidemic form of that disease.

Causation.—The susceptibility of the mucous membrane of the small intestine to acute inflammation, after infancy, is slight. It may be produced by excesses in the use of stimulating food and alcoholic drinks, by poisoning with acrid substances, and by the use of drastic purgatives. It is sometimes attributable to the action of cold upon the body when heated and perspiring. Fatigue and debility will co-operate with these causes. But, like inflammation seated in other parts, it may be developed without any appreciable causation.

Diagnosis.—Acute enteritis is to be discriminated from dysentery, gastritis, colic, peritonitis, and typhoid fever. The discrimination from dysentery is sufficiently easy, if the inflammation be limited to the small intestine. Assuming that the local symptoms are sufficient to denote inflammation somewhere within the abdomen, the absence of the characteristic dysenteric evacuations, of tenesmus, and of tenderness in the tract of the colon, suffices to exclude dysentery. The only room for doubt is when more or less inflammation of the large intestine is superadded to the enteritis. In such cases, the diagnosis of enteritis is to be based on the existence of the symptoms of this disease for some days prior to the occurrence of the symptoms of dysentery, and on the predominance of the enteritic symptoms. The cases in which the supervention of dysentery renders this differential diagnosis in any degree difficult are extremely rare.

Nausea and vomiting, if unusually prominent, may suggest acute gastritis. But the symptoms of acute gastritis are of a much graver character than those of acute enteritis, and they point distinctly to the stomach as the seat of the disease. This disease may generally be excluded without difficulty. The two diseases, however, may be combined. The inflammation, in some cases, perhaps, extends from the small intestine to the stomach; and, in cases of poisoning with acrid substances, the local effects of the latter may be produced within the small intestine as well as in the stomach.

Colic is a functional affection characterized by intense pain, without tenderness or febrile movement, and is oftener accompanied by constipation than diarrhœa. These points are sufficient for its exclusion.

As regards the local symptoms, acute enteritis approximates to acute peritonitis more closely than to any other affection. But, as a rule, there is a marked disparity in the intensity of the symptoms in these two affections. The pain, tenderness, and tympanites common to both, are, in the great majority of cases, notably greater in peritonitis. Diarrhœa, which is the rule in enteritis, occurs exceptionally in peritonitis. Rigidity of the abdominal muscles, which is one of the diagnostic symptoms of peritonitis, is wanting in enteritis. Moreover, the constitutional disturbance, as denoted by frequency of the pulse, prostration, etc., is much greater in peritonitis. Attention to these points renders the differential diagnosis, in most cases, sufficiently easy.

The abdominal symptoms in typhoid fever may lead the physician to suppose that disease to be simply enteritis; and, on the other hand, a primary enteritis may be supposed to be typhoid fever. Typhoid fever is to be excluded by the absence of the diagnostic symptoms which attend its slow development, and its progress, viz., cephalalgia, epistaxis, bronchitis, the rose eruption, and mental aberration. Moreover, the adynamic symptoms in typhoid fever are generally greater than in simple acute enteritis, while the enteric symptoms are less marked.

Prognosis.—Acute enteritis, after infancy, in the majority of cases, is not a disease of great gravity. If it be not associated with any other important affection, and the patient be not of feeble constitution, a favorable prognosis may generally be entertained. The disease, however, sometimes ends fatally. This is to be apprehended when the pulse becomes feeble and frequent, the prostration marked and delirium is developed, the local symptoms persisting. The mode of dying is by slow asthenia, as in cases of dysentery.

Treatment.—The indications for treatment may be embraced in a few

words. An efficient purgative is generally, at first, advisable. Afterward, opium in some form is to be given sufficiently to relieve pain and diarrhœa. It may be administered by either the mouth or rectum, or, alternately, in both modes. It is to be given in doses proportionate to the urgency of the symptoms, and graduated according to its effects. Fomentations over the abdomen by means of poultices, the water dressing, or spongio-piline, are useful. Moderate stimulation of the surface of the abdomen by sinapisms or liniments is appropriate. General or local depletion by bloodletting is very rarely, if ever, called for. Mercury, as an alterative remedy, or given to "improve the secretions," is not to be recommended. The supporting treatment is indicated in proportion to the duration of the disease and the tendency to failure of the vital powers. The diet at first should be restricted and bland; but alimentation is, of course, important if supporting measures be indicated.

Subacute and Chronic Enteritis.

Chronic enteritis, save as connected with tuberculosis, is much more infrequent after infancy than the acute form of the disease. The symptoms are the same as in acute enteritis, but less marked. Anodyne and astringent remedies are indicated, with moderately revulsive applications to the abdomen, tonic remedies, and a nutritious but carefully regulated diet.

Subacute enteritis, not becoming chronic, is of frequent occurrence, arising either from dietetic errors or an arrest of digestion by exposure to cold, over-exertion, etc. It is not easy to distinguish, practically, cases of transient subacute enteritis from cases of functional diarrhœa; nor is it of much practical consequence to make this discrimination, since the indications for treatment in either case do not materially differ, embracing mild purgation, followed by anodyne remedies and regulation of the ingesta. Enteritis, acute, subacute, and chronic, is described by some authors under the name *intestinal catarrh*. Here, as in other connections, the term catarrh is not adopted, inasmuch as it seems to be superfluous, and its use leads to confusion. Authors who treat at length of intestinal catarrh, embrace under this head cases which I shall notice in connection with diarrhœa and intestinal dyspepsia.

ACUTE GASTRITIS.

A remarkable change has taken place within the last quarter of a century in the opinions of physicians respecting the occurrence of acute inflammation of the stomach. It was formerly supposed to occur frequently. According to Broussais, whose doctrines, for a time, were accepted by many, inflammation of the mucous membrane of the stomach and small intestine (gastro-enteritis), constitutes the disease in all the essential fevers, and exists in most, if not all, cases in which symptomatic fever becomes developed. Reasoning *à priori*, it would seem that gastritis must be a frequent disease. This would be inferred from the quantity of ingesta which this organ daily receives, the various stimulating and irritating substances which enter into the alimentary supplies, its great functional activity, the alternations during and between the acts of digestion as regards the quantity of blood which it contains, and its extensive glandular arrangement. But late pathological and clinical researches have shown that acute inflammation in this situation is one of the rarest of diseases. Its existence as a spontaneous disease has even been denied. It is developed spontaneously, but so infrequently that many physicians of long experi-

ence have never met with an example of it. Valleix was able to collect only seventeen authenticated cases for analysis.[1] What is known of the disease is chiefly derived from cases in which it has been produced traumatically, that is, by the direct contact of acrid or corrosive poisons. It should be added that the term acute gastritis is understood to denote gastric inflammation of such intensity as to place life in imminent danger. As will be seen in treating of subacute gastritis, the inflammation in some cases of the latter affection approximates closely to acuteness, and, in fact, the line of demarcation between acute and subacute gastritis is fixed somewhat arbitrarily. Acute gastritis, as here considered, embraces only the most severe of the cases included by recent French and German authors, *e.g.*, Niemeyer and Jaccoud, under the name acute gastric catarrh.

Anatomical Characters.—If the disease destroy life quickly, as it sometimes does, marked redness, arborescent and punctiform, may constitute the chief morbid appearance. This appearance, however, may be produced by hyperæmia incident to venous obstruction arising from lesions of the liver or heart, or of both organs. It is to be taken as evidence of inflammation when the hyperæmia is limited to, or especially marked in, the stomach; when it is not associated with hepatic or cardiac lesions, and when the symptoms of gastritis had existed during life. If, however, life be not quickly destroyed, in conjunction with the redness, the mucous membrane and submucous tissue are notably softened, this change being observed in situations where it is not attributable to the action of the gastric juice. The mucous membrane is thickened, and the surface is usually covered with an abundance of mucus. The organ is contracted. The rugæ are few or wanting. If the disease have been produced by a caustic poison, such as some one of the corrosive acids, cyanide of mercury, etc., portions of the membrane which have come into contact with the poison present either eschars or ulcerations following the separation of sloughs. The destruction of tissue may not be limited to the mucous membrane, but may extend to all the coats, leading sometimes to perforation. The inflammation in cases of poisoning by the essential oils, or by any of the acrid poisons, is sometimes accompanied by diphtheritic exudation. In cases of poisoning, the action of the irritant or caustic substance ingested occasions more or less inflammation and perhaps sphacelation within the pharynx and œsophagus. The inflammation in cases of acute gastritis may extend into the duodenum.

Clinical History.—Acute gastritis gives rise to intense pain of a burning character, referred to the epigastrium, together with a painful sense of constriction, the pain shooting into the chest. The pressure of the diaphragm upon the stomach in inspiration increases the pain, and hence the breathing may be costal, and the number of respirations per minute is increased. Nausea and vomiting are prominent symptoms. In some cases the stomach is intolerant of water or the blandest liquids, even in very small quantities. The vomited matter is muco-serous, of a greenish color, the presence of bile being evident from the bitter taste, and not infrequently it is sanguinolent. The acts of vomiting occasion great suffering. The thirst is frequently, but not always, intense. The desire for cold water is sometimes so irresistible, that the patient is not deterred from drinking it by the painful acts of vomiting which it provokes. Tenderness on pressure over the epigastrium is marked. The pulse is more or

[1] Guide du Médecin Practicien.

less frequent and small. The temperature of the skin is moderately, and sometimes considerably, raised. The bowels are constipated except in cases of poisoning. Dysphagia and aphonia are occasional symptoms. The tongue presents no special morbid appearances. The mind is depressed, and the expression is anxious and haggard. If life be not speedily destroyed, and the disease run on to a fatal termination, vomiting of black, grumous, coffee-ground matter is likely to occur. Toward the close of life the contents of the stomach are ejected by acts of regurgitation rather than by vomiting. The prostration becomes extreme. Hiccough occurs. The pulse becomes very frequent and thready. Coldness of the surface is marked. The mode of dying is by asthenia. The career of the disease is rapid. Data are not available for determining the average duration. In fatal cases, death takes place usually within a few days; and it takes place in some cases within twenty-four hours, being produced in such cases apparently by shock. In a case reported by Dr. T. C. Finnell, at a meeting of the New York Pathological Society, in which a young girl took for self-destruction an infusion made by steeping in warm water a box of lucifer matches, death took place in six hours. If the disease end in recovery, improvement in all the symptoms takes place slowly; convalescence is gradual, and the inflammation may persist in a chronic form. In cases of gastritis produced by the corrosive poisons, if perforation of the stomach occur, the symptoms of peritonitis are added. In a case of spontaneous acute gastritis which came under my observation, slight jaundice occurred toward the close of life. The examination, after death, in this case, showed that the inflammation extended into the duodenum.

Pathological Character.—The stomach, aside from its office as a receptacle of the ingesta, is to be regarded as a glandular organ, furnishing daily a large quantity of an important secretion—the gastric juice. In its reluctance, so to speak, to take on acute inflammation from the internal and inappreciable causes which give rise to the so-called spontaneous inflammations in other situations, it resembles other glands, such as the liver, pancreas, kidneys. In the extremely rare instances in which acute inflammation is spontaneously developed in this situation, it does not differ in pathological character from acute inflammation seated elsewhere in a mucous structure. The gravity of the disease depends on the physiological relations of the stomach. Acute gastritis produced, traumatically, by the action of caustic or irritant poisons, is developed like inflammation from the action of the same local causes in other situations.

Causation.—Exclusive of the action of irritant and corrosive poisons, it is difficult to say what causes may give rise to acute gastritis. It may be produced by excessive indulgence in alcoholic drinks, especially when taken without food, but the alcohol in these cases doubtless acts as a local irritant. The same remark will apply to the over-ingestion of highly stimulating food. Various causes mentioned by writers, such as copious libations of cold water, intense moral emotions, were supposed to produce the disease in cases in which the diagnosis was based upon insufficient ground. In a well-marked case which has fallen under my observation, the patient was an habitual drinker, but the attack was not referable to a debauch. The patient attributed the disease to lying in a cold cellar. In this case, the evidence of the disease was based on the appearance after death, as well as the clinical history. I have known the disease to follow a debauch, and prove rapidly fatal.

Diagnosis.—The symptoms of acute gastritis are strongly diagnostic. There is greater probability of the disease being incorrectly supposed to exist, than of its being mistaken, when existing, for other diseases. Vomiting, however frequent and persisting, is never alone sufficient evidence of gastritis. I have known a case of chronic meningitis with few symptoms referable to the head, but with persistent vomiting, to be treated for acute gastritis, and the error not discovered prior to the autopsy. Peritonitis, if accompanied with vomiting, may assume an appearance of gastritis, but the diffusion of tenderness over the abdomen, the tympanitic distension, and the rigidity of the abdominal muscles, generally suffice for this differential diagnosis. Dr. Stokes has known gastritis to be mistaken for pneumonitis, but physical exploration of the chest should enable the physician to detect or exclude the latter affection. The author just named enforces the danger of overlooking gastritis developed after a debauch. I can testify, from my own experience, to this liability to error. Many years ago, in hospital practice, my attention was called to a patient who had been drinking to excess, and who was supposed, without close examination, to be affected with incipient delirium tremens. On my visit the following day, the case had ended fatally, and an examination after death revealed the existence of acute gastritis.

With a view to appropriate treatment, and, also, in a medico-legal point of view in certain cases, it is desirable to determine from the symptoms, whether acute gastritis be attributable to poison. This is always to be suspected, owing to the great infrequency of the disease as otherwise produced. Burning in the throat is complained of, if a caustic or corrosive poison have been taken, and the local action of the poison may be seen in the mouth and fauces. The matters vomited contain blood earlier and in larger quantity, as a rule, if the gastritis be due to a poison. Diarrhœa is more apt to occur in cases of poisoning. If caused by a poison, the disease is developed suddenly, and inquiry is to be made to ascertain if the sudden development were not immediately preceded by a meal or the ingestion of something in the way of food or drink.

Gastralgia was formerly confounded with gastritis. The paroxysmal occurrence of pain, or its increase forming marked exacerbations, the absence of febrile movement, the occurrence of vomiting in some cases only, the absence of tenderness on pressure, and the ability to take food sometimes with relief of the pain, sufficiently characterize the former affection as neuralgic.

Prognosis.—The opinions of different writers differ respecting the gravity of this disease when it is idiopathic. As it is only within a few years that the diagnosis has been placed on a correct basis, and the disease being so infrequent, the number of reported cases is not sufficient for determining the rate of mortality. It is undoubtedly a disease of great gravity. It may destroy life quickly, within a few hours, the mode of dying being by rapid asthenia or shock. These cases, however, are exceptional. The mode of dying is generally by slow asthenia.

When the disease is due to the action of an irritant or corrosive poison, the danger will depend, other things being equal, on the amount of local injury. Death in these cases sometimes takes place within a few hours by rapid asthenia or shock, dependent, not so much on the amount of local injury, as on the inability of the system to tolerate it. In some instances life is prolonged for several days, although the local injury be very great. A striking illustration of this fact is afforded by the case of a man who, at the burning of the Eddystone Lighthouse in 1755, swallowed a

quantity of molten lead, which accidentally dropped into his mouth when looking upwards to observe the progress of the fire. This patient lived for several days, and, after his death, a lump of lead, weighing 7 ounces, 5 drachms, and 8 grains, was taken from the stomach.[1]

Treatment.—The indications for bloodletting are rarely, if ever, present in this disease. Bearing in mind that the danger is from asthenia, and that life is sometimes quickly destroyed, it may fairly be doubted if the abstraction of blood is in any case admissible. The first and most important object in the treatment is to secure for the inflamed organ as much rest as possible. With reference to this object, the less of anything introduced into the organ the better. To allay intense thirst, small pieces of ice may be swallowed, or iced water taken often, in a very small quantity at a time. The physician should resist the temptation to try in succession the host of remedies to allay vomiting, all of which will be likely to aggravate this distressing symptom. It is desirable to administer opiates in order to quiet the stomach and render the system more tolerant of the disease. The salts of morphia placed dry upon the tongue may be tried, and, if vomiting be provoked by this mode of administration, they may be sprinkled over a vesicated surface, or administered hypodermically, or some form of opiate given per enema. Fomentations or a small blister may be applied over the epigastrium. Cathartics are inadmissible for the same reason that Cayenne pepper would be an inappropriate topical application to an inflamed eye. The bowels may be moved by stimulating enemas. Mercury, either in large or small doses, is not indicated more than in a case of an extensive burn or scald of the integument. The importunities of the patient for an emetic are to be resisted. He may have a feeling as if the stomach were distended, or as if there were an accumulation there aggravating his distress. This feeling arises from the inflamed state of the membrane, as tenesmus is incident to inflammation of the rectum.

If the symptoms denote a tendency to death from asthenia, the powers of the system are to be supported. The stomach, however, will not bear alcoholic stimulants and concentrated nourishment. These are to be introduced into the rectum in quantities proportionate to the urgency of the symptoms. If, on the other hand, the progress of the disease be favorable, and supporting treatment be not urgently called for, bland nourishment may be cautiously ingested when the improvement in the symptoms renders it probable that food will be retained. Milk, with the addition of lime water, will be likely at first to be best borne, given in small quantities at short intervals. Other forms of food may be gradually added. After the inflammation has disappeared, the stomach will be left in an atonic condition, and remedies of a tonic character may be indicated during convalescence. If the acute end in the chronic form of inflammation, the treatment due to chronic gastritis is to be employed.

Acute gastritis caused by the acrid or corrosive poisons is to be treated after the plan just stated, with the addition of measures having reference to the evacuation and neutralization of the poisonous substance. Emetics are to be promptly given, and if they fail to act efficiently, the stomach-pump is to be resorted to, provided the poison be one which can be ejected. Arsenic, corrosive sublimate, alcohol, antimony, cantharides, copper, phosphorus, together with a great number of vegetable irritants, such as capsicum, gamboge, croton oil, etc., may be expelled from the

[1] Aitken, *op. cit.*, vol. ii.

stomach; but, if any of the corrosive acids have been taken, reliance must be placed on the prompt administration of antidotes. Antidotes are also to be given after the employment of emetics or the stomach-pump to effect the removal of acrid poisons. For details respecting the management of cases of poisoning, the reader is referred to works which treat of toxicology.[1] I shall simply subjoin, for the convenience of the practitioner, an enumeration of the antidotes for the more important of the poisons which act locally upon the stomach.

Arsenical Preparations: The hydrated sesquioxide of iron is the special antidote. It should be recently prepared, and given in large quantity. If this preparation be not immediately available, the sesquioxide or common red oxide of iron (crocus martis) may be given in its stead. Bouchardat advises to combine with the preparation of iron, magnesia, in order to promote the passage of the iron from the stomach into the intestines.

Corrosive Sublimate and other Salts of Mercury: The most reliable antidote is albumen, and the white of eggs is the best and most available article.

Salts of Copper: Albumen is an antidote. Iron reduced by hydrogen and the hydrated persulphate of iron are said to be antidotal, by Bouchardat, both to the salts of mercury and copper.

Tartar Emetic: Substances containing tannin in abundance, and magnesia.

Nitrate of Silver: Chloride of sodium.

Mineral Acids: Magnesia or chalk mixed with water or milk; the alkaline carbonates or soap.

Oxalic Acid: Magnesia, chalk; whiting or plaster scraped from the wall of an apartment may be given, mixed with water. Alkalies are not to be given.

Ammonia: Vinegar or any of the vegetable acids.

Potassa and Soda: The same.

SUBACUTE GASTRITIS.

Subacute gastritis, not becoming chronic, but of transient duration, occurs not infrequently. It is not easy to say with positiveness how frequently it occurs, because practically it is difficult to fix the line of demarcation between slight inflammation and merely functional disturbance in this situation. Subacute gastritis doubtless enters into certain cases of the affection which will be noticed in connection with functional disorder of the stomach, under the name acute dyspepsia. Subacute as well as acute inflammation, when not involving diphtheritic exudation, is called by some authors catarrh or catarrhal inflammation of the stomach. The term catarrh, however, is superfluous here as in other applications. It is to be noted that the secretion of mucus, in more or less abundance, is a physiological event in connection with hyperæmia during stomach digestion. In this respect the gastric mucous membrane differs from mucous membranes in other situations; the latter, as a rule, do not secrete mucus in abundance except in abnormal conditions. Subacute inflammation of the stomach is much more frequent in infants and young children than in the after periods of life. As here considered, reference will be had chiefly to the affection occurring subsequently to the period of infancy.

The degree of inflammation in different cases of subacute gastritis varies,

[1] Taylor on Poisons may be consulted for this purpose.

being either slight, moderate, or considerable, as evidenced by the local and general symptoms. Inasmuch as it never proves fatal *per se*, the opportunity of observing the morbid appearances *post mortem* is rarely offered. There is doubtless more or less redness from hyperæmia or congestion of the mucous membrane, but this may measurably or entirely disappear after death. The quantity of mucus is morbidly increased, and the contents of the stomach may, in consequence, have an alkaline reaction. The membrane is more or less thickened and softened, but it is difficult to determine to what extent the latter may be due to cadaveric change.

The local and general symptoms are marked according to the intensity of the inflammation. In cases in which the inflammation is slight or moderate, the appetite is impaired but not lost. The ingestion of food is followed by uneasiness or distress referred to the epigastrium, and by symptoms denoting indigestion, namely, flatulency, eructations, etc. Thirst is a symptom which is constant and is more or less frequent. Tenderness over the epigastrium and a furred or coated tongue are other symptoms. The urine is high-colored and loaded with the urates. In some cases there is constipation, and in other cases diarrhœa, the latter being due to intestinal indigestion. Pain in the head is a frequent, and sometimes a prominent symptom; and when connected, as it frequently is, with nausea, it is commonly known as "sick headache." There may be slight febrile movement, but it is frequently or generally wanting, except after the ingestion of food or stimulants.

When transient febrile movement is not thus produced, the pulse is usually feeble, and the extremities are apt to be cold. There is more or less general debility, but the sense of weakness exceeds the actual reduction of strength. The spirits are depressed, and the suffering may be considerable from malaise without any definite location of pain or distress.

This is a sketch of a class of cases which the practitioner meets with frequently, and which, together with cases of the affection to be considered in another chapter under the name acute dyspepsia, is popularly known as a "bilious attack."

If the gastric inflammation be greater, approximating in intensity to acute gastritis, the local and general symptoms are much more marked. There is suffering from gastric distress, and sometimes from a dull, obtuse pain in the region of the stomach. The epigastric tenderness is often considerable, anorexia is complete, with loathing of food and nausea. Vomiting is apt to be a prominent symptom. Mucus is vomited in abundance; and, if the efforts of vomiting be prolonged, bile is rejected. The patient experiences a temporary sense of relief after vomiting. He has a feeling as if the stomach were distended, and he is led to provoke and assist acts of vomiting by voluntary efforts with the idea that if the contents of the stomach were effectually discharged the relief would be permanent. This feeling arises from the inflamed condition of the membrane, and is analogous to the sensation connected with tenesmus in dysentery. Thirst is apt to be urgent, and cold drinks are craved. The tongue is coated at first, but, in the course of the affection, it may become clean and reddened. Either constipation or diarrhœa may exist. There is more or less febrile movement, with evening exacerbations, as shown by the pulse and axillary temperature; the latter, however, rarely exceeds 100° Fahr. Chilly sensations and rigors are common, continuing for a few seconds and recurring irregularly. Cephalalgia is generally marked, and in some cases is accompanied by a sense of tension, or a feeling as if the head would break. The debility is such that the patient keeps the bed.

There is often a sense of great prostration, with depression of spirits and sometimes a notable degree of mental apathy. In cases of maximum severity, subacute gastritis so closely approximates to acute gastritis that there is scarcely a well-marked line of division between the two forms of the disease. It has been usual to embrace under the name acute gastritis, only cases in which the intensity of the disease is such that life is in imminent peril; whereas, in the severest cases of subacute gastritis, the prognosis is always favorable. This distinction, it must be confessed, is somewhat arbitrary, and its strict pathological propriety is perhaps questionable.

In cases of subacute gastritis with considerable febrile movement, the disease is sometimes called "gastric fever." As the fever is symptomatic, or secondary to the gastric inflammation, there is the same impropriety in using the term gastric fever as in calling pneumonitis "lung fever."

Subacute gastritis, if the inflammation be slight or moderate in degree, is usually of short duration, convalescence taking place in a few days. If the inflammation have considerable intensity, the duration of the disease is from a week to three weeks. If the inflammation persist much beyond the latter date, the affection is to be considered as having become chronic.

Subacute gastritis, in some cases, is evidently of dietetic origin. It is sometimes attributable to the decomposition of ingested aliment, owing to a deficiency of gastric juice, or to the quantity of food ingested being out of proportion to the digestive capability of the stomach, and to the ingestion of food difficult of digestion, or in which putrefaction had begun prior to the ingestion of it. These causes, however, much oftener give rise to merely functional disorders, namely, vomiting, acute dyspepsia, crapulous colic and diarrhœa than to a well-marked attack of gastritis. Persons who are habitually addicted to over-indulgence in eating, or to highly seasoned dishes and the free use of condiments, are doubtless more liable to this affection than others, as a consequence of a gluttonous meal, or when, from any cause, stomach digestion is arrested. The affection sometimes follows a prolonged debauch. The habitual free use of spirits begets a liability to it. It occurs especially among drunkards. It may be caused by any of the acrid or irritant poisons not taken in sufficient quantity to produce acute gastritis. In a certain proportion of cases the causes, both remote and proximate, are not apparent.

An affection to which subacute gastritis is closely affiliated is that to be considered under the name acute dyspepsia. Gastric inflammation doubtless enters into certain cases of the latter affection, but the functional disturbance is disproportionately great as compared with the amount of inflammation, and is not to be accounted for by the latter; hence, the propriety of considering it a functional affection of the stomach. The differential diagnosis of these affections is not, practically, of great importance. The symptoms of gastritis are present in certain cases of remittent fever, and, perhaps, they proceed actually from subacute inflammation of the stomach in these cases. The symptomatic phenomena of remittent fever, however, are sufficiently distinctive to render its discrimination from simple gastritis easy. Cases of ephemeral fever, or febricula, are to be discriminated by the want of proportion between the febrile phenomena and the gastric symptoms. Cases of continued fever, typhus and typhoid, very rarely present symptoms of gastritis with sufficient prominence for the differential diagnosis to be a matter of question. In general, the diagnosis of subacute gastrititis is not difficult. In making this statement it is to be borne in mind that reference is had to the disease as occurring after infancy and early childhood.

In the treatment of subacute gastritis, rest of the inflamed organ is of primary importance. If the inflammation be but slight or moderate, it will suffice to place the patient on a diet reduced in quantity, consisting of milk with lime water, and farinaceous articles. In cases of greater severity, complete abstinence for two, three, or four days may be advisable; the vomiting and loathing for food will be likely to secure this end without any injunctions on the part of the physician.

In the mean time, if the symptoms denote exhaustion, the patient may be supported by nutritious enemas. The abstraction of blood, either locally or by venesection, is never indicated. Benefit may be derived from sinapisms or a blister over the epigastrium. Emetics and purgatives are contraindicated. The sensations of the patient may lead to a desire for both, especially the former, but they do not effect any desirable object, and their local action upon the inflamed membrane will do harm. If the bowels be constipated, simple enemas may be employed. Mercury is not indicated more than in cases of inflammation affecting the mucous membrane or other portions of the digestive system. On the other hand, remedies to soothe the inflamed membrane, and to allay vomiting, are indicated, namely, bismuth in a solid or in the liquid form, hydrocyanic acid, hyoscyamus, and especially the salts of morphia. Small pieces of ice may be swallowed, or iced water given in a small quantity at a time and often repeated, if found to be grateful to the patient. Carbonated water is not only taken with comfort, but appears to be useful. The alkaline carbonates are considered useful by Niemeyer, as diminishing the viscoscity of the gastric mucus, and thus favoring its removal. It is, however, not certain that the latter object is of great importance. The bicarbonate of soda is the alkaline carbonate to be preferred, and it is best given in carbonated water.

It is important not to continue the abstinence from food or a great reduction of diet too long. As soon as nutritious articles of food are well tolerated by the stomach, they are admissible. The improvement of diet should be made gradually and tentatively. During convalescence the mineral acids are useful as tonics; and, after the inflammation has ceased, other tonics may be appropriate. Patients who are spirit-drinkers should be told of the connection of the disease with their habits.

CHRONIC GASTRITIS.

Chronic gastritis is not infrequent, although by no means so common an affection as was supposed some years ago. Chronic functional disorders were formerly considered as inflammatory. It is not always easy to discriminate clinically between chronic inflammation and the functional affections embraced under the name dyspepsia. The differential points involved in this discrimination will suffice for the clinical history and diagnosis of the affection.

Symptoms denoting indigestion or difficult digestion are present in cases of chronic gastritis, but these, alone, are in no wise diagnostic, since they alike exist in cases of dyspepsia. Pain may not be present, and, if present, is not distinctive. A burning sensation or a feeling of heat in the gastric region, is somewhat diagnostic. Tenderness over the epigastrium is somewhat diagnostic, provided it be limited to that region and constant, that is, not present merely during the process of digestion or when the stomach is distended. Thirst is diagnostic, if habitual, that is, present, not only during the process of digestion, but at other times. The appetite is much oftener impaired in connection with chronic gastritis than in cases of dys-

pepsia; the appetite is generally preserved, and often craving, in the latter. The nutrition is oftener defective in cases of chronic gastritis; dyspeptics often preserve their weight unimpaired. In chronic gastritis, stimulating articles of food, such as meat and condiments, are not as well borne as bland aliments, the reverse being the case in cases of dyspepsia. Alcoholic and other stimulants produce gastric distress in cases of chronic gastritis, whereas, they often relieve distress incident to merely functional disorder. Nausea and vomiting are more apt to occur in connection with chronic gastritis, excluding cases of so-called acute dyspepsia and certain cases of functional disorder characterized by vomiting; in ordinary cases of dyspepsia, nausea and vomiting are not common. A slight grade of febrile movement is sometimes observed in chronic gastritis, and very rarely in a purely functional disorder.

The diagnosis is to be based on the combination of more or less of the foregoing differential points. In making the diagnosis, certain structural affections of the stomach are to be excluded, viz., carcinoma and ulcer. The diagnostic symptoms of these affections will be considered in the next chapter.

Chronic gastritis may follow an inflammation of the stomach developed spontaneously or produced by the acrid or corrosive poisons. It may proceed from excesses in eating or spirit-drinking, and, on the other hand, long fasting or too rigid dieting may give rise to it. Andral found the stomach inflamed, with ulcerations, in dogs destroyed by starvation.[1] Dr. Stark, who fell a victim to experiments in dietetics in 1769, had symptoms of gastritis developed during prolonged abstinence. Arsenic introduced into the system by absorption from an external wound, gives rise to gastritis, as ascertained by Brodie and verified by the observations of others. The venous congestion of the stomach which is an effect of diseases of the liver involving portal obstruction, more especially cirrhosis, and of diseases of the heart, favors the production of gastritis if exciting causes be added. Chronic gastritis occurs in certain cases of renal disease involving uræmia; the probable explanation being that the carbonate of ammonia which is formed from the decomposition of the urea eliminated by the gastric mucous membrane, acts as a local irritant.

The first point in the treatment is the removal of dietetic causes which may have originated or which tend to perpetuate the affection. The patient is to be placed on a bland and easily-digested diet, consisting of milk, eggs, stale bread, soft-boiled rice, and other farinaceous articles—articles which are digested in the small intestine. Meat and stimulants are to be interdicted. For a short time it may be advisable to reduce the quantity of food below the amount which the wants of the system require. Food should be taken in small quantities and at shorter intervals than in health. Moderate counter-irritation over the epigastrium appears to be useful. The remedies to be administered are few. Solicitations for emetics and cathartics are to be resisted. Patients are apt to declare that they are "bilious," or that there exists "foulness of the stomach," and, hence, that they need evacuant medicines. But in place of medicines which, from their irritant action, will tend to increase or prolong the inflammation, remedies to soothe the inflamed membrane are indicated, viz., small doses of morphia, hyoscyamus, hydrocyanic acid, bismuth, etc. After the inflammation has ceased, functional debility or atony remains. Tonics

[1] *Vide* Budd on the Stomach. Inflammation of the stomach, however, is not an invariable effect of starvation. It was not found by Martigny in dogs starved to death.—Magendie, *Journal de Physiologie*, tome viii.

and improved diet are then required. It is a point of delicacy to determine when to make this change in the treatment. It is like resorting to "passive motion" in cases of fracture or dislocation. The change is to be commenced tentatively, and continued, or not, according to the effect.

DUODENITIS.

In acute gastritis the inflammation, as already stated, may extend into the duodenum. This is also true of subacute and chronic gastritis. But it would appear, from the symptoms, that subacute duodenitis may occur as a separate affection, not connected, on the one hand, with gastritis, nor, on the other hand, with inflammation of the lower portion of the small intestine. The diagnostic symptoms are, obscure pain, uneasiness or distress occurring some hours after the ingestion of food, that is, after it passes from the stomach into the duodenum, and tenderness below the epigastrium over the site of the affected organ. Duodenitis, occurring either separately, or in connection with gastritis and enteritis, is interesting and important as standing in a causative relation frequently to jaundice. The jaundice is to be explained by obstruction either from swelling of the mucous membrane of the duodenum at the opening of the ductus choledochus, or from an extension of the inflammation into the duct. The latter is the more probable explanation. The treatment is the same as that of subacute gastritis. This affection will again be referred to in the consideration of jaundice.

It is a curious fact, ascertained by Curling, that a sloughing ulcer is apt to take place at the upper part of the duodenum, within a few days after the occurrence of a severe burn on the skin. Perforation may occur under these circumstances. Ulceration of the duodenum is not a constant effect of an extensive burn. Wilkes states that he failed to find it in several cases which had come under his observation.

PHARYNGITIS.

Affections of the buccal and guttural portion of the alimentary canal, namely, glossitis, the several varieties of stomatitis, etc., belong to surgery. I shall accordingly pass them by with the exception of a brief notice of pharyngitis. Certain affections of the mouth, prevailing especially in early life, are embraced among the diseases of children, and are considered in treatises devoted to these diseases.

Acute inflammation of the pharynx may be limited to the mucous membrane, or associated with inflammation of the tonsils or of the submucous areolar tissue. Associated with inflammation of the tonsils, it constitutes the affection called *tonsillitis* and commonly known as *quinsy*. The tonsil on one side only or both tonsils may be affected. Acute tonsillitis generally ends in suppuration; an abscess forms, and purulent matter, sometimes fetid, and nauseous to the taste, is discharged after a period varying in different cases from two to ten days. It is a very distressing affection in consequence of the pain and difficulty of deglutition. The enlargement of the tonsils, when both are affected, is such that the pharynx appears to be closed. The mucous membrane covering the tonsils and the arches of the palate is reddened and swelled. The affection, however, is attended with danger only from the very slight liability to the occurrence of œdema of the glottis. Of this I have met with a single example. An attack of tonsillitis is sometimes attributable to exposure to cold, but it often occurs without any obvious causation. The causation involves a

predisposition to the affection, and persons predisposed are apt to experience repeated attacks. The treatment consists of poultices to the neck, or the water-dressing, the inhalation of the warm vapor, and anodynes to render the condition of the patient less uncomfortable. Milk is the form of nourishment best taken. When the abscesses point they may be opened, and the patient is thus relieved sooner than if they were left to break.

Acute pharyngitis, giving rise to inflammation and suppuration in the areolar tissue between the mucous membrane of the pharynx and the vertebral column, constitutes the affection called *retro-pharyngeal abscess*. The point of departure in the development of this grave affection, however, is rarely, if ever, the mucous membrane; it may occur, traumatically, from the penetration of a sharp piece of bone contained in food, or as secondary to caries of the vertebræ.[1]

Inflammation of the pharynx with an exudation of lymph, constituting what is called diphtheritic, pseudo-membranous, or exudative inflammation, occurs in connection with two important diseases to be considered in another section, viz., diphtheria and scarlatina.

Ordinary or simple acute pharyngitis, that is, the inflammation limited to the mucous membrane, or erythematic, and unattended by the exudation of lymph, is an affection of frequent occurrence. It is one of the forms of "a cold." The inflammation may extend over more or less of the pharyngeal space and fauces. Its extent and intensity are to be ascertained by inspection of the throat, but it sometimes extends upward into the posterior nares, and lower in the pharynx than the eye can reach. It occasions more or less pain, especially in the act of swallowing, and the patient is annoyed by a constant disposition to swallow. At first the inflamed parts are dry, but, after a time, a secretion of mucus takes place, and this provokes efforts at hawking and expuition. If the inflammation extend low in the pharynx, coughing is excited. The cough is of a peculiar character, easily recognized and distinguished as a throat-cough, the forcible current of expired air being brought to bear on the pharynx. The limitation of the inflammation to the pharynx, or its non-extension into the larynx, is shown by the absence of huskiness or hoarseness of the voice. The tonsils may present a deposit of a white material in patches of greater or less size, which is a sebaceous secretion from the follicles in this situation. These white patches have a resemblance to diphtheritic exudation, and it is highly important to discriminate between the two. The follicular secretion forms a pultaceous deposit, not a membraniform layer like the deposit of lymph, and cannot be removed in strips like the latter. The patches are more prominent than those formed by a layer of lymph, and their borders are more abruptly defined. They are more easily removed than patches of lymph recently exuded, and they disappear spontaneously more quickly. Finally, on close inspection, the secretion will be seen to dip into the follicular depressions. The follicular deposit occurs without any abrasion of the mucous surface, but it is common for patients to consider the patches as ulcers.

Simple acute pharyngitis occurs as an epidemic affection, sometimes prevailing greatly and widely. It prevailed to a considerable extent in this city (New York) during the spring of 1864. In many if not most epidemics, the clinical history shows the affection to be a form of fever rather than simply a local inflammation. This was manifestly true of an epi-

[1] For an excellent article on retro-pharyngeal abscess, with a statistical table of 58 cases, by Charles M. Allen, M.D., *vide* N. Y. Journal of Med., Nov. 1851

demic which I studied in the western part of this State in 1857. From the results of an analysis of twenty-three recorded cases of that epidemic, the following conclusions were deduced: "The disease was an epidemic fever characterized by mild erythematic inflammation of the fauces as a constant local complication. Its character as essentially a fever is established by the febrile movement being in a marked degree out of proportion to the local affection; in other words, evidently not being symptomatic of the latter, and by its running a definite although a brief career. It was a fever of from three to five days' duration. Its epidemic character is sufficiently apparent. It prevailed extensively for about two months, reaching its acme gradually, declining gradually, and at length disappearing, affecting both sexes and different ages without notable discrimination. As an epidemic fever, its symptomatic features were very uniform. The affection of the fauces constituted the only positive character aside from the brief duration of the febrile career. The other symptoms uniformly present were only those incident to febrile movement, and the symptoms observed in a few cases only were incidental events, not intrinsic elements of the disease. The small white patches in the throat observed in a few cases do not establish any relation to the affection known as diphtheria. These were evidently due to follicular secretion. The occurrence of several cases repeatedly in the same family does not suffice to prove that the disease was propagated by contagion, since this fact is explicable on the supposition of the patients being equally exposed to an epidemic influence, and there being a marked discrepancy in the intervals separating the cases successively occurring in the same family."[1]

In the report from which the foregoing conclusions are quoted, facts are given which show conclusively that the affection was not scarlatina. It resembled influenza, save that the pharyngeal, and not the bronchial mucous membrane, was the seat of the local manifestation. It may be a question whether an epidemic fever with simple pharyngitis be not a form of influenza, or a variety of the disease characterized by pharyngitis with the exudation of lymph (diphtheria), or of the affection called epidemic erysipelas, popularly black tongue.

Simple pharyngitis, occurring as a sporadic disease, or as the anatomical characteristic of an epidemic fever, is a mild disease, having little or no tendency to end fatally. Œdema of the glottis is an accident which may occur, but it is extremely infrequent. I have met with one example of its occurrence in a case of sporadic pharyngitis. The therapeutical measures indicated are, mild purgation, followed by anodyne remedies, and quinia or the chlorate of potassa. Gargles of the chlorate or the nitrate of potassa may be employed, and to allay the dryness and irritation of the throat, a mucilaginous liquid, or glycerine, may be taken frequently in small quantity, or small pieces of gum allowed to dissolve in the mouth. Caustic or stimulating applications to the inflamed membrane are not called for.

Subacute pharyngitis, not becoming chronic, is very common, and is generally treated without the advice of a physician. It is generally sufficient to supply the absence of mucus, before secretion takes place, by mucilage or glycerine. Lumps of sugar soaked in salad-oil and allowed to dissolve in the mouth is a simple mode of palliating the local irritation. If other measures appear to be called for, those appropriate to the acute affection may be employed.

Chronic pharyngitis is, in my experience, an extremely common affection. It is generally a subacute affection at the beginning, and is de-

[1] Buffalo Medical Journal, vol. xii. p. 718.

veloped imperceptibly, so that, in most cases, when they first come under medical observation, there is reason to suppose it has existed for a considerable period. The membrane is more or less reddened, and irregularly thickened so as to present a granulated or mammillated appearance, especially marked on the posterior wall of the pharynx. Adhesive mucus is sometimes seen sticking to the part, when the throat is examined. This inflammation sometimes extends to the posterior nares, and the patient is then said to have catarrh. It may extend around the top of the larynx, but it has no tendency to pass into the laryngeal cavity. Occasionally, the mucous follicles are distended with sebaceous matter. The appearance is not sufficiently common to render the name *follicular pharyngitis* appropriate except as applied to certain cases.

The tonsils in some cases present white masses varying in size from that of a pin's head to a pea, either wholly imbedded in, or in part projecting from, the mouths of the follicles. I have met with cases in which the tonsils were very thickly studded with these masses. If removed mechanically, as may easily be done, they are sometimes quickly renewed. If not understood, the striking appearance of the throat in these cases may lead to the apprehension that the affection is more important than it really is.

Chronic granular pharyngitis in some persons occasions but little inconvenience. It is often found when the patient makes no complaint of any trouble in the throat. In other cases, it occasions more or less annoyance. An uncomfortable sensation is felt in the throat. The presence of adhesive mucus excites efforts of hawking and coughing. Partial obstruction of the Eustachian tubes may occur. The proximity of the inflammation to the larynx may give rise to a dry, hacking cough. The voice becomes slightly hoarse after considerable use in speaking or reading. The use of the voice is followed by a sense of fatigue in the vocal organs.

The affection is much more frequent in males than in females. It occurs most frequently after puberty, and in middle life. From its frequent occurrence among the clergy, it has been called *clergyman's sore throat;* but it is by no means peculiar to the clergy, occurring perhaps quite as often in persons of other callings. It occasions more inconvenience to clergymen than to others, from the necessity which they are under of using the voice in public speaking, and they are apt to be apprehensive lest it may incapacitate them from preaching. It may be doubted whether the use of the voice leads to the affection. It occurs especially among persons of sedentary habits who suffer from the wear and tear of continued application, without physical and mental relaxation. The number of persons in this country who overtask the powers of the system by steady labor in the office, the counting-house, or the work-shop, continued without intermission for many years, giving no time whatever to recreation, is very large. It is among those who in this way violate the laws of health that this affection prevails. It is accompanied with symptoms denoting impairment of the general health. Patients complain of debility, and a want of their accustomed energy; they are generally depressed in spirits, and have forebodings of loss of health; they are very apt to fancy the existence of some serious disease, especially pulmonary consumption, and it is sometimes difficult to convince them that the latter disease does not exist. Dyspeptic ailments frequently coexist. Palpitation is not uncommon.

The affection tends to continue. It is usually long persisting. In many of the cases which I have seen it had existed for many years. But there is no tendency to eventuate in an affection of the air-passages, or in

tuberculous disease. Patients with this affection rarely become tuberculous; its existence is, to some extent, evidence of the non-existence of tuberculosis. It is a popular notion that the affection does denote a consumptive tendency, and this notion is encouraged by the host of irregular practitioners who, within late years, in this country, have made diseases of the throat a specialty. The mental condition of patients with this affection renders them an easy prey to quacks.

The treatment, to be effective, must have reference to the system. After considerable experience I have come to regard topical applications as generally of little or no curative value. In some cases, however, a solution of the nitrate of silver, of tannin, or of iodine, appears to be useful in the way of palliation. As regards the mode of employing remedies topically, inhalations carry the medicated application too far, while gargles do not carry it far enough. Projecting a spray of medicated solutions into the throat is an efficient mode, but a simple and satisfactory plan is to use a small mop made of soft linen, which is to be dipped in the medicated liquid and carried into the throat. The application by the latter mode can be easily made by the patient. The remedies which exert a curative influence in certain cases of bronchitis are sometimes useful, namely, the iodide of potassium, the bromide of potassium, the chlorate of potassa, and the hydrochlorate of ammonia. Alteration of the habits of life is first in importance. Relaxation, recreation, and out-of-door life are far more efficacious than medicines, and the latter are of little use without the former. When circumstances permit, relinquishment of business for a time for travel or rural occupations is of signal benefit. Tonic remedies may often be advantageously conjoined with proper hygienic management. Tonics, to be efficacious, should be continued for a long period, and the form of tonic changed from time to time. The diet should be nutritious. The object of treatment, in short, is to restore the general health.

The diagnosis of chronic pharyngitis is, of course, sufficiently easy. Inspection is alone necessary. But it is important to discriminate simple chronic pharyngitis from that dependent on syphilis. The latter is to be suspected from the local appearances (ulcerations and the so-called mucous patches), and discriminated by these appearances in conjunction with other secondary syphilitic phenomena, together with a knowledge of the fact of syphilis having existed.

In the follicular variety of chronic pharyngitis, the matter which accumulates in the follicles may be ejected by coughing, in the form of round, solid pellets which are sometimes supposed to be tubercles or pulmonary calculi. They are to be distinguished from the latter by being easily broken down with pressure, by being unctuous to the touch, and emitting, when crushed, a fetid odor.

PAROTIDITIS. MUMPS.

The affection commonly known as mumps may be appropriately noticed in this connection, as seated in an organ accessory to the buccal cavity. The parotid gland appears to be the seat of the disease, but it evidently involves a constitutional morbid condition and a special causation. The local affection consists of enlargement of the gland together with swelling of the surrounding parts, soreness to the touch, pain especially in mastication, the pain frequently extending to the ear and in other neighboring situations. The submaxillary gland is sometimes involved. The swelling in the site of the parotid pushes outward the lower part of the ear.

Œdema of the face is sometimes associated. The amount of swelling of these several parts varies in different cases; if considerable or great, it causes a notable change in the physiognomy. The skin generally is not discolored. The affection may be limited to one side, or both sides may be affected. In the latter case, usually the two sides are affected successively, with an interval of a day or two, but in some cases both sides are simultaneously seized.

The disease is frequently ushered in by a light chill, or by chilly sensations, and in its progress it may be accompanied with moderate febrile movement, diminished appetite, pain in the head, and general malaise. The disease continues for four or five days. The swelling, pain, and soreness gradually subside and disappear. The inflammation has no tendency to suppuration nor to continue in a chronic form. An abundant perspiration sometimes takes place at the time of convalescence. Occasionally, during the progress of the disease, or when the affection of the parotid is about to disappear, swelling, pain, and soreness of one or both of the testes occur. This must be extremely rare. I have met with but a single example. In the female, it is stated the mammary gland and the labia majora are liable to become affected. I have never met with an example. When parts, other than the parotid, are involved, it is not from a metastasis, but from the operation of the same internal morbid condition which occasions the parotiditis.

The communicability of this disease is generally admitted, but it has been denied by some writers of high authority, for example, Valleix. It prevails, at certain times and places, to such an extent as to be an endemic disease. But this is true of diseases which are exclusively propagated by contagion, *e. g.*, smallpox. Persons between twenty and thirty years of age are most susceptible to the infectious miasm, but it occurs not infrequently under puberty. Males are more susceptible than females. It is one of the diseases which affect the same person but once.

The prognosis is always favorable. The disease, except that it occasions considerable discomfort, is trivial. In the way of treatment, it claims only soothing embrocations, and the application of flannel, cotton batting, or wool to the neck, with some anodyne remedy if the pain be considerable. Bloodletting, purgation, or other of the so-called antiphlogistic measures are not indicated. The popular apprehension of danger from "taking cold" in this disease, is based on the idea that, if the affection of the parotid be arrested, a metastasis is apt to take place. There is little ground for this idea, but a patient probably passes through the disease more comfortably by avoiding exertion and exposure.

Parotiditis occurs as an occasional complication of typhus and typhoid fever. Under these circumstances it is a widely different affection from mumps. Suppuration takes place in the great majority of cases, the abscesses evacuating either externally or into the meatus auditorius, and frequently there is considerable sloughing of the areolar tissue. As a complication of fever it is attended with much suffering and danger. Virchow teaches that in the non-suppurating form, that is, in mumps, the inflammation has its point of departure in the ducts, whereas, in suppurating parotiditis, the inflammation is seated in either the substance or the areolar tissue.

CHAPTER III.

STRUCTURAL AFFECTIONS OF THE STOMACH.

Induration. Softening. Gastric Ulcer. Carcinoma of Stomach. Dilatation of Stomach. Degeneration of the Gastric Tubules.

HAVING considered the inflammatory affections of the mucous membrane lining the different sections of the alimentary canal, the structural affections of the stomach and intestines next present themselves for consideration. Directing attention, first, to the stomach, the following are the structural affections to be noticed: Induration, softening, ulceration, carcinoma, dilatation, and lesion of the gastric tubules. These several affections will be briefly considered in the order in which they have just been enumerated. For a fuller consideration of these affections than is consistent with the scope of this work, the reader is referred to works on morbid anatomy and treatises devoted specially to diseases of the stomach.

INDURATION (SCLEROSIS).

Induration, or sclerosis, denotes a structural change characterized by increased density and thickness not dependent on carcinomatous disease. The name has the merit of not implying anything respecting the pathological character of the lesion. The affection is apt to be confounded with scirrhus. It is due to a morbid product or growth of a fibroid character, seated primarily in the submucous areolar tissue. The firmness and weight of the stomach are increased. The firmness may be such that the organ does not collapse by its own weight. The thickness of the walls is sometimes greatly increased. The gross and microscopical appearances show the induration to depend on the addition of a substance analogous to that of fibrous tumors, or the structure of a cicatrix. The substance appears to be like that between the hepatic lobules in cirrhosis, and the affection has been called cirrhosis of the stomach. Brinton has proposed to call it *linitis*. Habershon calls it fibroid degeneration. It is supposed to be an effect of chronic inflammation of the submucous areolar tissue.

The lesion may be more or less extensive. The whole of the organ may be affected, or it may be limited to a small portion. In the latter case, the pyloric extremity is apt to be the seat. The danger connected with the affection depends much on its extent and situation. If the pylorus be involved, it induces stricture, and this renders it a serious lesion. If the lesion be extensive, the incapacity of the stomach for dilatation stands in the way of the ingestion of a sufficiency of food.

The existence of this lesion is not denoted by any distinctive symptoms. In a case under my observation, in which, after death, the walls of the organ were found to be from half an inch to an inch in thickness everywhere except at the pyloric third, the patient, up to a few weeks before death, supposed he was simply dyspeptic, his ailments not being sufficient to lead him to seek for medical advice. In this case, the organ formed a resisting movable tumor, felt through the abdominal walls, and the dis-

ease was supposed to be carcinoma. If pyloric obstruction be produced, vomiting, from an accumulation of the ingesta in the stomach, is a prominent symptom. Dilatation of the stomach may ensue. The immediate cause of death in such cases is inanition.

The affection is rare. Most writers concur in regarding it as occurring chiefly in spirit-drinkers, and very rarely in persons under forty years of age. Habershon states that it is met with in temperate persons of either sex, and in early life. If seated at the pylorus and involving stricture, it may be suspected when the evidence of pyloric obstruction is afforded by vomiting of accumulated ingesta and dilatation of the stomach, provided carcinoma can be excluded. The absence of a tumor to be felt through the abdominal walls, and of hemorrhage from the stomach, renders it probable that carcinoma does not exist. If the affection do not involve pyloric obstruction, the diagnosis can hardly be made with any degree of certainty. If the thickened and hardened stomach can be felt through the abdominal walls, there are no means of determining positively that the affection is not carcinoma. The long duration of the affection, the absence of the cancerous complexion, and the non-existence of cancer in other situations, are the points involved in this differential diagnosis.

The treatment embraces remedies to palliate irritation of the stomach, abstinence from spirits and other stimulants, and careful regulation of the diet.

SOFTENING. (GASTRO-MALAXIA. GASTRO-MALACIA.)

Softening of the mucous tunic of the stomach has been already mentioned as one of the anatomical characters of gastritis. It is observed in cases in which the other appearances and the history during life show it to be non-inflammatory. The softening may be limited to the mucous membrane or extend to the other coats of the stomach. Limited to the mucous membrane, the walls of the organ are thinned; the affected coat cannot be removed in strips, but is easily scraped away, and in some cases the membrane is converted into a pulpy layer, the disorganization being complete. This form of softening has been studied particularly by Louis, who calls it *pultaceous softening*. Softening of the several coats has been described very fully by Cruveilhier under the name *gelatiniform softening;* also by Billard. These and other French writers regard the latter as a special lesion characteristic of an individual disease affecting chiefly children and accompanied by symptoms analogous to those belonging to the affection known with us as cholera infantum.

It is probable that non-inflammatory softening may sometimes, during life, be the result either of a defective nutrition of the membrane, or of the chemical action of the gastric juice. A deficient supply of arterial blood, from embolism or other causes, may lead to softening here as in other situations; and, according to Pavy, the gastric juice, under these circumstances, may act as a solvent, this action, in health, being prevented by the alkalinity of the blood. But in the great majority of cases, both forms of softening are to be regarded as not morbid, but due to the action of the gastric juice after death. The changes are post-mortem, resulting from self-digestion by the stomach. John Hunter was the first to establish the fact that, under certain circumstances, the stomach undergoes digestion after death. He observed several cases in which perforation was produced by this cause, the contents of the stomach escaping into the peritoneal cavity. This has since been abundantly shown by experimental observations on inferior animals. Perforation of the stomach from this

cause in fishes is common. Post-mortem digestion is found especially in cases of sudden death occurring shortly after the ingestion of a meal, but it has also been observed in cases of sudden death when the stomach was empty, and even perforation has taken place under the latter circumstances. Softening, more or less in degree from this cause, is common after death from various diseases, varying very much in different cases according to a diversity of circumstances connected with the state of the stomach at the time of death, all of which are not as yet understood. In a case of death at Bellevue Hospital from fracture of a cervical vertebra, the stomach and the diaphragm were digested so that the contents of the stomach were found in the left pleural cavity. In this case the patient had taken only liquid nourishment for two days before his death. It is supposed that alcoholic stimulants, given shortly before death, may prevent the solvent action of the gastric juice. A high temperature favors post-mortem softening. It will not be likely to take place in cold weather, nor when bodies are placed in ice. The case just referred to, however, occurred in the month of October, and the body was in a cold place. It is met with oftener in the bodies of children than of adults. According to Virchow and others, softening, whether occurring during life or after death, may be due to the products of the fermentation of the ingesta, the action being purely chemical and independent of the gastric juice. The ingesta in which fermentative processes may take place and lead to this post-mortem effect, are milk and the amylaceous articles of diet. The presence of an abundance of mucus in the stomach is supposed to favor, by catalytic influence, these processes.

Post-mortem softening is more likely to occur at the cardiac than at the pyloric portion of the stomach, but it may extend to the latter and even to the duodenum. The gastric juice may regurgitate into the œsophagus and lead to perforation of this tube, and the escape of the contents of the stomach into the cavity of the chest has been repeatedly observed. The softened portions of the stomach are white, or of a bluish-white color, if the bloodvessels are empty, but if these contain blood it is rendered dark by the action of the gastric juice, and, escaping through the coats of the vessels, it gives to the tissues a darkish color. The softened parts have an acid reaction, and are free from the odor of putrefaction, the gastric juice acting as an antiseptic. This latter point distinguishes from softening due to putrefactive change. If perforation take place, the aperture is a "ragged hole," with pulpy edges. The organs with which the gastric juice comes into contact after escaping from the stomach, viz., colon, spleen, liver, etc., may present softening. Perforation of the stomach from self-digestion is not to be confounded with the destructive effects of corrosive poisons, and the knowledge of the former is highly important to be borne in mind in making autopsies after sudden death, in cases involving a suspicion of poisoning.

GASTRIC ULCER.

Ulceration of the stomach is among the anatomical characters of acute gastritis, especially when the latter is produced by corrosive poison; but it occurs independently of acute gastritis, the inflammation, if it exist, being limited to the ulcerated space or spaces. The ulcer varies in size in different cases, being sometimes so small as to be discerned with difficulty, and sometimes of the size of a half-dollar, a dollar, or even considerably larger. If small in size, it has generally a round or oval form, and presents an appearance, in some cases, as if a portion of the tissues had

been punched out. This kind of ulcer, especially, is apt to eat through the several coats of the stomach, and is distinguished as the round, eroding or perforating ulcer. The ulcerated space is largest in the mucous membrane, next in the muscular tunic, the ulcer being funnel-shaped. The liability to perforation followed by fatal peritonitis, and to another accident, viz., erosion of a vessel of the stomach, giving rise to a hemorrhage which may prove fatal, the difficulty of cicatrization, if these accidents do not occur, and the interference with the functions of the stomach which the ulcer occasions, render the affection one of much gravity.

Gastric ulcer is not an extremely infrequent affection. Brinton's researches show that it is found after death in an average of 5 per cent. of persons dying from all causes.[1] Jaksch, quoted by Niemeyer, found in 2330 autopsies, ulcer in 57, and cicatrices denoting ulcers which had healed in 56; making the ratio of an ulcer, either existing or having existed, as one to every 20 subjects.

In the greater proportion of cases a single ulcer exists, but in the proportion of one to every 5 cases, two or more ulcers are found after death. The situation, in the great majority of cases, is the posterior surface of the stomach towards the pyloric extremity. Brinton found the situation to be as just stated in the proportion of 86 in 100 cases. Adhesion of the stomach, at the site of the ulcer, to adjacent parts, the pancreas, left lobe of the liver, etc., is frequently found, due to circumscribed peritonitis excited by the proximity of the ulcer. This is conservative, rendering perforation less frequent than it would otherwise be.

The clinical history embraces, as the most prominent symptoms, pain, tenderness on pressure, vomiting, and hemorrhage from the stomach. These are the important symptoms in a diagnostic point of view. Pain is very rarely wanting. It is burning or gnawing in character, coming on directly, or soon after, the ingestion of food, and continuing until the contents of the stomach have either passed into the duodenum or been ejected by vomiting. The quickness with which the pain follows the ingestion of food is a diagnostic point; if due to simple indigestion or neuralgia, it generally occurs after a greater or less interval from the time of taking food. It is situated at, or near, the epigastrium, and is generally confined to a small space. A similar gnawing pain in the back, between the shoulders, is not uncommon. The probable cause of the pain is irritation of the ulcerated space by the contact of the ingesta and the gastric juice. The pain from this cause is especially marked after the ingestion of stimulating articles of food or drink, and when, from indigestion, the contents of the stomach undergo chemical changes. Pain may also be caused by circumscribed peritonitis, and by the traction of adhesions which have resulted from peritoneal inflammation. The latter causes may account for the exceptional occurrence of pain irrespective of the ingestion of food. The pain caused by the action of the gastric juice is felt directly after eating, because the secretion of the juice is excited by the presence of food in the stomach. Tenderness on pressure over the epigastrium is almost invariably present, confined, like the pain, within a small area, and varying considerably in degree in different cases. Vomiting is a very constant symptom, occurring after a period from the time of taking food, varying in the different cases, the act of vomiting usually not violent but complete, and the ejection of the contents of the stomach followed by notable relief. Mucus may be expelled, in more or less abundance, with the ingesta, show-

[1] Brinton's work on diseases of the stomach contains elaborate statistical researches on this subject; see, also, a monograph on this subject by the same author.

ing inflammation of the mucous membrane surrounding the ulcer. As respects vomiting, much will depend on the quantity and kind of food ingested. Indigestible and stimulating articles are more likely to provoke it, as well as to increase the pain, than aliments bland and easy of digestion. Hot substances are not as well borne as cold. Hemorrhage, as shown by the vomiting of blood in greater or less quantity, is a symptom of frequent occurrence. The vomiting of blood generally occurs after a meal. The hemorrhage is sometimes so abundant that life is lost from this cause. Cases have been reported in which life was lost from hemorrhage, although no blood was vomited, the stomach being found after death filled with clots. The blood vomited is dark or grumous from the action of the gastric juice, provided the vomiting does not immediately follow the hemorrhage. In view of the diagnostic value of hemorrhage as a symptom, Brinton enforces the importance of an examination of the matters vomited with the microscope, although the gross appearance may not denote hemorrhage, and he states that blood-globules may be found in the sediment of a comparatively clear liquid. The stools also should be examined for the gross and microscopical appearance of blood, for hemorrhage may take place without vomiting, the blood passing into the intestinal canal. Profuse hemorrhage occurs especially in connection with the small perforating ulcer.

The bowels, in cases of gastric ulcer, are generally constipated, a symptom easily understood in the cases in which vomiting is a prominent symptom. Amenorrhœa, in the female, is common, but, if there have been much hemorrhage, this symptom is a result of the loss of blood. There is little foundation for the idea that hemorrhage from the ulcer occurs vicariously in the place of menstruation, but the latter ceases, or is deficient, as in cases of chlorosis, or anæmia produced by hemorrhages elsewhere, or from other causes.

The pathological character of gastric ulcer is not fully settled. Whether it be a result simply of a circumscribed inflammation, or whether it be due to a non-inflammatory sloughing process, as held by Rokitansky, is still an open question. Nor is it certain whether it commences on the mucous surface, or has its point of departure within the tubules. It has been conjectured that small ecchymoses within and beneath the mucous membrane may precede and give rise to ulceration. Virchow attributes the perforating ulcer to obstruction of an arterial branch and consequent mortification of the walls within the space nourished by the branch which has become obstructed, the action of the gastric juice upon the mortified part co-operating to effect the separation, leaving the ulcer. The arterial obstruction may be due either to embolism, thrombosis, or calcareous degeneration of a branch of the gastric artery.

Exclusive of the form which is especially distinguished as perforating, gastric ulcer occurs chiefly in persons of middle and advancing life. The truly perforating ulcer, on the other hand, occurs in young girls, and particularly in young maid-servants. Statistics show that females are more liable to ulcer, the proportion being as 2 to 1. Clinical observation fails to show any dependence on particular habits of diet, or other causes, nor has it any known relationship with other affections. It may be stated, however, that persons of feeble or impaired constitution are more liable to it than the robust.

The diagnosis of gastric ulcer may be made with great certainty, provided the diagnostic symptoms are present, viz., pain of a burning or gnawing character limited to a circumscribed space in the epigastrium, with tenderness also circumscribed, the pain especially felt after the inges-

tion of food, and especially after certain kinds of food, vomiting occurring during the process of stomach-digestion, and followed by relief, and, finally, gastrorrhagia or hæmatemesis. Analogous symptoms, it is true, may be present in cases of cancer of the stomach, but there are points of contrast involved in this differential diagnosis, which will be noticed presently in considering cancer. Moreover, the absence of a tumor appreciable through the abdominal walls goes far toward the exclusion of cancer. Chronic gastritis and ulcer have symptoms to some extent in common. But in chronic gastritis pain is less prominent, vomiting does not occur so frequently, and hemorrhage is wanting. In cases of gastralgia, the pain might suggest the idea of ulcer. But the pain in gastralgia is not aggravated, and, on the contrary, often relieved by the ingestion of food; tenderness over the epigastrium is not present, but the pain is often relieved by pressure; vomiting is an occasional symptom only, and hæmatemesis does not occur. In cases of merely functional disorder, pain, vomiting, and hæmatemesis are all wanting. Hæmatemesis, it is to be borne in mind, is not alone evidence of ulcer. It occurs, irrespective of disease of the stomach, in certain cases of cirrhosis of the liver. It is the union of the several symptoms just named that renders the diagnosis complete. These diagnostic symptoms, however, are not united in all cases of gastric ulcer. Hemorrhage is not invariably present; vomiting is not always a prominent symptom and may be wanting; pain and tenderness are not in all cases marked—the affection, in short, is sometimes latent, more or less difficulty or disturbance of digestion only being manifested. Under these circumstances, a positive diagnosis cannot be made. A strong suspicion of the existence of the affection may, in some cases, be reasonably entertained, when the symptoms do not warrant a positive diagnosis.

Gastric ulcer proves fatal in different modes. One of these is by perforation, fatal peritonitis being induced by the escape of the contents of the stomach. This accident would take place oftener than it does, were it not for the adhesion of the stomach to the adjacent organs as a result of circumscribed peritonitis. Perforation is most apt to occur when the ulcer is situated on the anterior surface of the stomach. According to Brinton, it occurs in the proportion of 1 to 7 or 8 cases. It is most likely to occur in the ulcer distinguished as perforating, *i. e.*, the small, round, punched ulcer, although not limited to this kind of ulcer; hence, it occurs oftenest in females between sixteen and thirty years of age. The perforation generally takes place after the ingestion of a meal, or in the act of straining or sneezing, or in some sudden and forcible movement of the body. In some cases peritonitis, following perforation, occurs without having been preceded by any symptoms pointing to the existence of ulceration of the stomach.

Another mode in which it proves fatal is by hemorrhage. Life may be slowly destroyed by the continued escape of blood, or repeated attacks of hemorrhage, or the loss of blood may be so rapid as to destroy life quickly. According to Brinton, death from hemorrhage occurs in the proportion of 1 to 20 cases. Fatal hemorrhage occurs much oftener in the male than female. As an example of fatal hemorrhage arising from an extremely minute perforating ulcer, the following case, communicated to me by the late Dr. W. W. Reid, is of interest:—

A young woman, a chambermaid, æt. 25, for a year or more had had pain in the stomach, at times so severe as to disable her from her work for a few days. During the week previous to the 12th ult. she had more pain than for some months. There was marked tenderness over the epigastrium at all times. On the 12th ult., she went to bed more unwell

than usual, and before falling asleep became sick at the stomach and vomited. On the morning of the 13th, she arose and dressed herself, but was faint and obliged to go to bed. At this time she discovered that what she had thrown up in the night was blood, and the quantity was reported to be about three pints. In the afternoon she again vomited a pint or more of blood. On the 14th and 15th she again vomited blood. From the 19th to the 22d, she was considered better and improving, but was unable to be raised up without fainting. On the 22d she had something like a convulsion, and became comatose. She continued in this condition until the morning of the 23d, when she had another convulsion, and died during the afternoon of this day. Shortly before death she threw up an inky liquid. On examination after death, the only morbid appearance in the stomach which was at first observed was a small patch three or four inches square, in which the mucous membrane was injected. This was situated about three inches from the cardiac orifice. On close inspection in the centre of this patch, a small ulcer was discovered resembling the puncta lachrymalis when large. The blunt end of a common silver probe readily entered the opening and passed directly into a branch of the gastric artery. Dr. Reid, in his remarks on the case, says that the ulcer was detected almost by accident, on account of its minuteness, and in view of the general healthy appearance of the gastric mucous membrane: he suggests that in similar cases the existence of a minute ulcer may have been overlooked.[1] The occurrence of gastrorrhagia is sometimes, like perforation of the stomach, not preceded by symptoms denoting the existence of gastric ulcer, the latter being latent as regards the diagnostic points which have been named.[2]

Another mode in which it proves fatal, is by inanition. Death takes place by slow asthenia when the stomach is so intolerant of ingesta that aliment sufficient for the support of life is not retained. In other words, patients are gradually starved to death, provided life be not cut off by some other disease which the system may be rendered unable to resist in consequence of the debility incident to the stomach affection.

The duration of the affection is very variable. Death sometimes takes place from perforation or hemorrhage within a few weeks, or even a few days, after the time when the symptoms first denoted gastric trouble; or, as already stated, perforation and hemorrhage may occur when previous symptoms denoting gastric ulcer were wanting. But if these accidents do not prove the immediate cause of death, life is usually prolonged for many months, and it may be for very many years. Brinton states that he has notes of one case in which probably a continuous open ulcer existed for 35 years, and of two cases in which the duration was 30 years, together with three or four of 20, four or five of 15, and several of 10, 7, 5, and 4 years' duration. It is not uncommon in the course of this affection for the symptoms, from time to time, to subside, or even to disappear, and subsequently to return. These remissions are probably due to healing of the ulcer which afterward again opens.

Gastric ulcer, although a serious affection, is by no means incurable. Brinton estimates that a cure takes place in about one-half of the cases which occur. This estimate is based on the number of instances of cicatrized ulcer found in autopsical examinations. The cicatrices are generally small or of moderate size, but in some instances they occupy considerable space; in the latter case, they may induce contraction and

[1] This case is given more fully in the *Buffalo Medical Journal*, vol. ii. p. 641, 1846.
[2] *Vide* case reported by Dr. C. Murchison in Trans. Patholog. Society of London, 1871.

considerable deformity of the stomach. Situated at the pyloric orifice, they sometimes lead to stricture.

The treatment of gastric ulcer embraces the following objects: *First*, and most important, securing for the stomach as much rest as is compatible with a proper amount of nutrition; *second*, the arrest of hemorrhage and the palliation of suffering; and, *third*, the employment of remedies to promote cicatrization.

The first of these objects is to be secured mainly by regulation of the diet. The patient is to be nourished by those nutritious articles of food which will be best retained by the stomach, and give rise to the least inconvenience. Milk and farinaceous substances will be best borne. As remarked by Budd, the articles which, combined out of the body, would make a soothing poultice for an ulcer on the skin, are the most likely to be tolerated by the stomach in cases of this affection. Condiments, alcoholic stimulants, solid and indigestible food of any description, meat, and, according to Chambers, sugar, should enter as little as possible, or not at all, into the diet. The quantity of food taken at a time is a point of importance. The rule is, a small quantity at a time, the intervals regulated according to circumstances. Experience in each case is, of course, to guide in this regard, and also in the choice of articles. Milk and other liquids should be taken cold. Limewater added to milk renders it less likely to occasion disturbance. Quietude of the body is to be enjoined, more especially during the process of digestion. It is desirable to limit, by habits of quietude, the waste of the tissues, in order that the demand for nutritious supplies may be proportionably limited.

In some cases the most judicious and careful regulation of the diet proves unsuccessful. Vomiting is constant, and the pain is severe so long as the stomach contains food. It is evident that the ulcer is not healing, and the patient may be in danger from inanition. Under these circumstances, an attempt may be made to secure for the stomach complete rest, as regards the ingestion of food, by the introduction of nourishment exclusively by the rectum. Brinton advises this procedure for a few days, from time to time, in severe cases. It may sometimes be continued for weeks, and even months. In a case of supposed ulcer at Bellevue Hospital, I pursued this course for three weeks—enemas of the essence of beef and milk being given every four hours through the day, and nothing taken into the stomach but small pieces of ice. The pain and vomiting were greatly diminished during this period, and the patient lost but little ground as regards strength. She did not suffer from hunger, but thirst was a source of some inconvenience. The course would have been longer continued, but for the irritability of the rectum, in consequence of which, at length, the nutritious enemas were immediately returned. On returning to alimentation by the stomach, she bore food better than before, and after some months she improved sufficiently to leave the hospital. I saw her several months after she had left the hospital, and she reported herself quite well.[1] My friend and former colleague, Prof. Rogers, of Louisville, has related to me a case in which a child was supported by enemas for a month, the case being one of poisoning with caustic potash, death taking place at the end of the month. In the *American Journal of the Medical Sciences*, in 1852, Dr. D. L. Pierce, of Pennsylvania, has reported a case of supposed gastric ulcer, the patient being sustained wholly by enemas

[1] Eight years afterward this patient re-entered hospital, with a renewal of the diagnostic symptoms of gastric ulcer, having had good health up to several months before her readmission.

for three consecutive months. The following statements, taken from the report, contain the material points in this remarkable case:—

The patient was a female, aged 26. She appeared to vomit everything ingested a few moments after eating. Circumscribed tenderness existed over the epigastrium. She was emaciated, feeble, and had been confined to the bed for three months. Purulent matter was ejected from the stomach with the food, and sometimes by itself. Severe pains were referred to the epigastrium. Remedies, as well as food, being quickly vomited, Dr. Pierce proposed to her to submit for a month to entire abstinence as regards the ingestion of food by the stomach, and to try the plan of taking nourishment by enemas, to which she assented. A half-pint of good lamb or mutton broth was injected every three hours. For the first week she took by the mouth several times a day a teaspoonful of gum-arabic or pure water, but after the first week this was discontinued. Dr. Pierce says that he has no doubt of the strict compliance, on her part, with the plan of treatment adopted. The epigastric region was vesicated, and the surface sprinkled with morphia. During the first week vomiting of purulent matter occurred several times daily, but during the three following weeks it diminished, and she was in all respects more comfortable. It was resolved to continue the plan for another month. The vomiting of purulent matter during this month occurred only occasionally, and the improvement continued. During this month Dr. P. believes not a morsel or drop of anything passed her lips. It was agreed to continue the plan for still another month. The improvement progressed rapidly, and by the middle of the month all evidence of gastric disease had disappeared. She began before the month ended to take a little water and mucilage in small quantity. She had gained in flesh and strength during this plan of treatment. On returning to the introduction of food by the stomach, the symptoms did not return, and two years afterward the patient was in the enjoyment of excellent health.

Hemorrhage is to be arrested by small pieces of ice swallowed, and by the application of cold to the epigastrium if the loss of blood be considerable. Astringent remedies may be given if the stomach will retain them. Pain will require the use of opiates, the form being selected which is found on trial to be the least objectionable. It may be administered per enema, epidermically, or hypodermically, if not tolerated by the stomach. Moderate counter-irritation over the epigastrium by liniments, or by dry cupping, is useful. Opiates may also serve, in some cases, to alleviate the vomiting. The subcarbonate of bismuth is a very useful remedy in some cases, given in scruple doses three or four times daily.

It is doubtful whether any remedies exert a direct effect to promote cicatrization. The nitrate of silver and other remedies have been given with the expectation that they will exert a topical effect upon the ulcer. Clinical observation appears not to furnish evidence of their utility in this way. Cicatrization is promoted indirectly by remedies which arrest the peristaltic movements of the stomach and quiet the irritability of the organ, in other words, remedies which have reference to the first object of treatment, viz., securing as much rest as possible; and for this end opium in some form is the most effective remedy. Cicatrization is also promoted indirectly by tonic remedies if these be borne. Local blood-letting is injurious by lowering the vital forces. Mercurialization is objectionable on the same ground. Cathartics are hurtful on account of their direct action. Constipation, if it exist, is to be relieved by enemas.

When an improvement in the symptoms renders it probable that the ulcer is healing, great care in diet is important to prevent a relapse, and

it is to be borne in mind that remissions are apt to take place, followed by a renewal of all the symptoms. Care is necessary for some time after the healing appears to have been completed; the patient is not to be considered as safe for some time after apparent recovery.

CARCINOMA OF STOMACH.

Cancer of the stomach is far more infrequent than gastric ulcer. According to Brinton's researches, primary cancer of the stomach was found in only 81 of 8468 autopsies, or in the proportion of about one per cent. Yet cancer in this situation appears to be as frequent as elsewhere. Brinton deduces from his own researches and those of others, that, of all primary cancers, one-third are seated in the stomach. The same author estimates the liability to ulcer as four times greater than the liability to cancer. As a rule, cancer when seated in the stomach is primary; that is, it is not preceded by cancer in some other situation. The pylorus is the part most frequently affected, viz., in the proportion of 3–5. The cardiac orifice is the seat in the proportion of ten per cent. As exceptions to the rule, cancer may be seated at a point between the two orifices, oftener in the line of the small than the great curvature. The point of departure for the morbid deposit or growth is usually the submucous areolar tissue. As a rule, to which there are very few exceptions, cancer of the pylorus is limited to the stomach, not extending to the duodenum, but cancer of the cardiac orifice extends more or less into the œsophagus. The cancer in the great majority of cases is of the scirrhus variety. Brinton's statistics show the proportion to be seventy-two per cent., whereas, the proportion in which the cancer is medullary is eighteen per cent., and the proportion of colloid cancers about ten per cent. In the progress of the cancerous affection, ulceration of the mucous coat is apt to take place, so that symptoms of ulcer and cancer are combined. Sloughing away of portions of the cancerous mass is not uncommon. Perforation of the stomach sometimes occurs. It occurred in 21 of 507 cases analyzed by Brinton. The cancerous affection leads to adhesion of the stomach to adjacent organs. Stenosis or stricture at the pyloric or cardiac orifice is another effect, playing an important part in the production of symptoms. The opening of vessels is still another effect, giving rise to hemorrhage. The carcinomatous growth, especially when seated at the pyloric orifice, forms a tumor of greater or less size. Obstruction at this orifice induces dilatation of the stomach and hypertrophy of its muscular tunic. Commonly, obstruction at the cardiac orifice leads to contraction of the organ.

The symptoms which make up the clinical history of this affection are as follows: Impaired appetite, or anorexia, is generally more or less marked, but in some cases the desire for food is maintained. Pain is usually more or less prominent, and the character of the pain is frequently lancinating. The pain is sometimes gnawing, as in ulcer, and, in these cases, ulcer may have occurred as secondary to the cancer. Tenderness over the epigastrium may, or may not, exist. Vomiting is a frequent symptom, but it occurs less frequently than in cases of simple ulcer, and at a later period after taking food, provided the affection be not seated at the cardiac orifice. The vomiting, if the cancer be at the pylorus, may be chiefly due to obstruction at this orifice, and consequent accumulation. The cryptogamous plants, sarcinæ and torulæ, may be found in the vomited matters when these have undergone fermentation within the stomach. Blood is not infrequently found in the vomited matters, gene-

rally in small quantity, and having the coffee-grounds appearance. Purulent or sanious matter is frequently vomited. With these symptoms referable to the stomach are associated progressive loss of weight and strength, anæmia, not infrequently febrile movement, usually constipation but occasionally diarrhœa, and in some cases jaundice. The last-named symptom points to the probable occurrence of secondary cancer affecting the liver.

With respect to the pathology and causation, nothing is to be added here to what has been stated already in the first part of this work. Cancer in the stomach, as elsewhere, involves a constitutional predisposition or diathesis, and a morbid change preceding the local affection, or a cachexia. Statistical researches do not appear to show that the development of the affection is favored by particular habits of life or any appreciable causes. The causation has reference to age. The liability to the affection prior to the age of forty is small. In the great majority of cases it occurs between fifty and sixty. The liability to it diminishes after sixty, and is small after seventy. Males are affected more frequently than females, the proportion being as 2 to 1. The occurrence of cancer of the uterus in the female compensates for this difference. The transmission of the cancerous predisposition or diathesis by inheritance is well established. Facts, also, appear to show that a predisposition to cancer seated in the stomach may be inherited. A well-known example is the case of Napoleon Bonaparte, whose father, and a sister also, died of cancer of the stomach.

Cancer of the stomach is to be discriminated from merely functional disorder, or dyspepsia, and chronic gastritis. In merely functional disorder, pain and vomiting are symptoms rarely as prominent as they are generally in cancer. The ailments in dyspepsia are seldom so protracted; they do not lead to the same amount of emaciation, feebleness, and pallor; hæmatemesis and the vomiting of purulent matter are wanting. The same is true of chronic gastritis. Persistent disturbance of digestion, especially if accompanied by pain and vomiting, leading to considerable loss in weight, diminution of strength, and anæmia, in a person between forty and sixty, should always excite strong suspicion of cancer, although blood and pus have not been vomited. Cases of gastralgia lack all the diagnostic features of cancer except pain. Gastric ulcer is liable to be confounded with cancer, and in view of the great difference as regards prognosis, it is desirable to discriminate between these affections. They present certain points in contrast as regards the symptoms. In cancer the appetite is more impaired than in ulcer. Vomiting is more uniformly present in ulcer; it occurs earlier after the ingestion of food, and, in general, is evidently due to the irritation caused by the presence of food. In cancer it is present in only a certain proportion of cases; it does not follow so soon after taking food, if the cardiac orifice be not obstructed, and is frequently due to the mechanical distension of the stomach owing to the pyloric obstruction. Hemorrhage is more constant, and is apt to be more profuse in ulcer. If the patient be a young girl, the chances are much in favor of ulcer: and, at any age, if the patient be a female, ulcer is more probable than cancer. The pain in cancer is apt to be lancinating, in ulcer burning or gnawing. The duration of the local symptoms is of importance in this differential diagnosis; if the symptoms have existed for a long period, the chances are in favor of ulcer rather than cancer. Age is to be considered in the diagnosis, cancer occurring rarely before forty.

Considerable importance has been attached to a peculiarity of complexion which has been supposed to denote the cancerous cachexia, consisting of pallor with a faint tint of yellow or green, the conjunctiva

remaining unaffected. It has been called a waxy complexion. This is sometimes well marked in cases of cancer, but it is by no means always present, nor is it pathognomonic when marked. If members of the family have had cancer, this fact is entitled to some weight in the diagnosis. So, also, is the coexistence of cancer in some other situation.

In some cases of cancer there are few or no symptoms denoting any serious affection up to a short time before death. Like gastric ulcer, it is sometimes remarkably latent, the patient appearing to suffer only from moderate or slight dyspeptic ailments, the appetite remaining unimpaired, the strength not failing, and the aspect indicating health. Watson cites several examples of this kind. Some time ago I was accustomed to meet frequently a gentleman supposed to be simply delicate and a dyspeptic, who, at length, was seized with severe gastric symptoms and died after a short illness. At the post-mortem examination, the pylorus was found to be the seat of a large cancerous tumor which involved a large portion of the stomach. As another example, I visited in consultation an aged gentleman who died a few days afterward with unmistakable cancer of the stomach, and in this case it was only within a few days that the patient had had a suspicion of anything more than a trivial disorder.

In the latent cases just referred to, and also when the differential diagnosis relates to ulcer and chronic gastritis, much importance belongs to the discovery, or otherwise, of an abdominal tumor in the site of the pylorus or stomach. Exclusive of the cases in which the cardiac orifice is the seat of the cancer, a tumor is discoverable by physical examination in the majority of cases. According to Brinton, it exists in 80 per cent. of all cases of cancer. The tumor is situated generally between the false ribs and the umbilicus, a little to the right of the median line. It may be movable or fixed. If movable, Valleix attaches considerable importance to its change of position, according as the stomach is distended or empty. The tumor varies in size from a pigeon's egg to the size of the closed hand. It is usually resisting, and the surface irregular or nodulated.

The presence of a tumor, if ascertained to be seated in the stomach, renders the diagnosis quite positive. But it may not be always easy to decide positively that the tumor is seated in the stomach. A cancerous tumor may simulate aneurism of the abdominal aorta. The characters of an aneurismal tumor are expansile pulsation, thrill, and murmur. A cancerous tumor may present, more or less marked, the same characters. It may present not only a single, but a double, murmur. How are the two to be distinguished from each other? An aneurismal tumor is rarely movable; it has usually a smooth outline, and may be diminished by pressure; the pulsation is felt laterally as well as on its anterior surface; by a change of position of the patient, as placing him on his hands and knees, the pulsation is not materially affected, whereas if the tumor be not aneurismal, its pressure on the artery is taken off and the pulsation may be found to cease. But aneurismal tumors do not always pulsate, and both thrill and murmur may be wanting. Under these circumstances, in this differential diagnosis, reliance must be had upon the diagnostic points relating to the history and symptoms. These are, of course, always to be carefully considered. Other tumors, from their situation are liable to be confounded with cancer of the stomach, viz., tumors connected with the left lobe of the liver and the pancreas, fecal tumors, etc. The distinctive characters of these will be considered in other connections.

Cancerous affection of the cardiac orifice, leading to stenosis or stricture, gives rise to symptoms quite different from those which accompany cancer of the stomach otherwise situated. Food accumulates in the lower

part of the œsophagus, and is regurgitated directly after deglutition. The obstruction, if considerable, interferes with vomiting as well as the ingestion of food. The food is regurgitated without change, and is devoid of the taste and odor of the gastric fluids. The patient is unable to take solid food, and is compelled to take liquids slowly and in small mouthfuls. If the stricture be great, death takes place gradually by inanition. A patient was admitted into Blackwell's Island Hospital, æt. 45, in a state of great exhaustion, and evidently very near death. He stated that for a long time he had been unable to take anything but liquids. The bowels were constipated, no dejection, according to the patient's statement, having taken place for a month. Death occurred twenty-four hours after admission. On post-mortem examination, the cardiac orifice was found to be the seat of cancerous disease which extended somewhat up the œsophagus. The cardiac orifice was so completely occluded, that a fine silver probe was passed with difficulty through it, and water poured into the œsophagus remained there. I met with a similar case, the inanition not so far advanced, at my clinic at the Long Island Hospital. Two additional cases have come under my observation since the first edition of this work appeared.

In these cases, a tumor is not discoverable. The symptoms are the same as in cases of stricture at the lower portion of the œsophagus from other than cancerous disease, and the differential diagnosis cannot be made with positiveness. Spasmodic stricture of the œsophagus may simulate contraction from either cancer or some other organic affection. The passage of a probang into the stomach will enable the practitioner to exclude the latter.

I have not referred to the microscopical examination of the matters vomited, in cases of suspected cancer, with a view to the discovery of the cancer cells. This test is only available at an advanced period of the disease, and then only in a very small proportion of cases, owing to the action of the gastric juice and the admixture of the exfoliated cancerous material with the ingesta.

The prognosis in cases of cancer of the stomach is as unfavorable as possible. If a cure be within the range of possibility, the probabilities are so vastly against it that we are not warranted in entertaining the least expectation of such a result in any individual case. A fatal termination is merely a question of time. Statistics show the average duration to be about a year. The maximum duration is about three years, and the shortest period is a month. Death occurs by slow asthenia. Perforation was the immediate cause of death in 21 of 507 cases analyzed by Brinton. Of 23 cases reported by Dr. Alfred L. Haskins, this was true of only five.[1]

The treatment has reference only to the prolongation of life and the palliation of symptoms. A diet, bland and nutritious, consisting of the articles of food which experimental trials, in each case, show to be best borne, taken in quantities and at intervals to be determined also by trial; remedies to relieve pain and quiet the irritability of the stomach; avoidance of cathartics and any measures which impair the vital powers—these are the points to be kept in view in the management of this distressing and hopeless affection.

DILATATION OF STOMACH.

Dilatation of the stomach is, in general, a lesion dependent on obstruction at the pyloric orifice. It enters into the anatomical characters of

[1] Am. Journ. of Med. Sciences, January, 1869.

certain cases of cancer, it is incidental to cicatrization of ulcers seated at the pylorus, it occurs in connection with pyloric thickening from fibroid growth, and it may be caused by the pressure of a tumor on the lower portion of the stomach. It takes place irrespective of obstruction at the pyloric orifice, but the instances are extremely rare. I have notes of two cases which have fallen under my observation, in which the dilatation was sufficient to form a notable projection of the epigastrium and upper part of the abdomen, there being no evidence of obstruction at the pylorus, save the existence of the dilatation. Both these cases were under observation for a short time only. But cases have been observed in which the dilatation was so great that the boundaries of the stomach embraced the greater part of the abdominal surface, causing enlargement of the abdomen as great as in hydro-peritoneum or an advanced period of pregnancy. The capacity of the organ has been known to be increased so that it would contain several gallons of liquid. The coats of the stomach, in these cases, are atrophied, especially the muscular coat, and the walls are sometimes as thin as paper.

In these cases of excessive dilatation, vomiting occurs after intervals of a few days, an enormous amount of matter being expelled, the matter consisting, in a great measure, of imperfectly digested aliment, which accumulates in consequence of the inability of the stomach to propel its contents into the duodenum. The vomited matter emits a putrescent odor, and frequently contains *sarsinæ* and *torulæ cerevisiæ*. The appetite is good or even voracious, but, owing to the accumulation of food in the stomach and its ejection by vomiting, the assimilation is not proportionate to the ingestion, and the body wastes.

The production of this lesion is attributed to atrophy of the muscular fibres, to paralysis of the stomach, and to habits of immoderate eating. Chambers is of opinion that in most cases of dilatation not the effect of mechanical obstruction at the pylorus, it is due to a congenital deformity. This author cites examples of its existence in persons who were accustomed to eat sparingly. The number of cases which are to be collected is, as yet, too few for analysis with reference to the causation and other points of investigation.

Dilatation of the stomach occasions an abnormal prominence of the abdomen especially marked at the epigastrium, and extending more or less below the umbilicus, according to the augmented size of the organ. The projecting tumor yields, at the upper part, a tympanitic resonance on percussion, having a characteristic gastric quality of sound. At the lower portion, if the stomach contain ingesta, there is flatness on percussion, and the relative situation of the flatness and tympanitic resonance changes as the position of the patient is changed from the vertical to the recumbent. On succussion, a splashing sound may be produced, analogous to that in pneumo-hydrothorax. This was marked in one of the cases under my observation. In the same case, when the patient swallowed liquid, metallic tinkling was heard with Cammann's stethoscope placed over the stomach, above the level of its liquid contents. If the abdominal walls be thin, the form of the stomach may be apparent, and its peristaltic movements may be seen. The enlargement varies at different times according to the variation in the contents of the stomach; it diminishes greatly or disappears after the complete expulsion of the contents by vomiting. A sense of fluctuation may be felt when the stomach contains considerable liquid. This is noted in the history of one of my cases.

Valleix states that paracentesis has been practised in a case of enormously dilated stomach, under the belief that the affection was hydro-

peritoneum. Physical examination of the abdomen should enable the practitioner to avoid this error. In hydro-peritoneum, the enlargement, if not uniform, is greatest at the lower part of the abdomen, the reverse being true of dilatation of the stomach. In hydro-peritoneum the enlargement is proportionate anteriorly and laterally; in dilatation of the stomach the anterior projection is greater than the lateral. In hydro-peritoneum flatness on percussion exists at the lower part of the abdomen; in dilatation of the stomach, intestinal tympanitic resonance will be likely to be found below the space which yields flatness, in the hypogastric and iliac regions. The variation in the enlargement, and its disappearance after complete vomiting, suffice for the diagnosis.

In the cases which I have observed, the affection was not attended by notable inconvenience. Vomiting did not occur in these cases. In cases of excessive dilatation, nutrition suffers from the accumulation of aliment in the stomach and its ejection by vomiting. Yet, it is stated by Valleix that there is no well-attested instance of death produced by simple dilatation.

Regulation of the ingesta as regards quantity, and tonic remedies constitute the appropriate treatment. Indigestible food and articles which, from decomposition, develop gas in abundance, should be interdicted. A diet of milk, containing grated ice, is recommended by Petrequin, who reported two of the cases collected by Dr. Haskins.

DEGENERATION OF THE GASTRIC TUBULES.

The degeneration of structure in different organs has been, within late years, much elucidated by microscopical researches. Of this fact, the affections of the liver, of the kidney, of the arteries, of the muscular tissue, etc., furnish striking examples. By the aid of the microscope, the intimate normal structure of different parts has been unfolded, as a point of departure for the study of abnormal deviations. Our knowledge of the gastric tubules has been in this way recently acquired. The stomach has been shown to contain an immense secreting surface furnishing an enormous amount of secretion daily. The glandular arrangement is essentially the same as in the other glands, for example, the kidneys, the difference being that the secreting surface is disposed in innumerable short tubules instead of convoluted tubes. Now, analogy would lead to the supposition that the tubules of the stomach may be the seat of disease and degeneration, as well as the tubes of the kidneys, or the secretory structure of other glandular organs. As yet, however, very little attention has been given to the study of the morbid conditions of the gastric glands. The subject has been referred to by two German writers, Engel and Wendl.[1] But to Hanfield Jones is due the credit of having broken ground in this new field of research. In a paper entitled "Observations of Morbid Changes in the Mucous Membrane of the stomach," Dr. Jones has tabulated the appearances of the gastric tubules in 100 stomachs, the subjects not selected, but taken consecutively, and dead with a variety of diseases.[2] The results go to show that here is a field the further cultivation of which may lead to highly important additions to our pathological knowledge.

[1] Chambers on Digestion and its Derangement.

[2] Medico-Chirurgical Transactions, vol. xxxvii. London, 1854. Further observations have been contributed by Dr. Wilson Fox, in *ibid.* 1857 and 1858; also, by Dr. Fenwick, in *ibid.* 1865.

Of the 100 examinations, in 72 the appearances denoted more or less degenerative change. Of these 72 cases, in 47 the degeneration was limited to a portion of the stomach, usually the pyloric portion, the tubules in the remainder of the organ being healthy. In 11 cases the extent of the affection was greater, but still moderate. In 14 cases the appearances denoted destructive changes extending over the greater part of the stomach. The appearances denoting degeneration within the tubules consisted of the deposit of black pigment and fatty granules, the presence of granular matter in the place of the normal epithelium, supposed to be the debris of the latter, and atrophy or loss of the epithelium. These changes are analogous to those observed in the degenerative changes which take place within the convoluted tubes of the kidney in cases of the chronic affections of these organs embraced under the name Bright's disease.

In the 14 cases in which the gastric tubules were extensively degenerated, the patients died with a variety of diseases, and it is not easy in so limited a number of cases to determine what symptoms were attributable to the affection of the stomach. It is not improbable that further researches will show these glands to be the seat of morbid conditions of great importance, as occurring alone or in association with other affections. There is room for the conjecture that the impairment of digestive power, the anæmia, debility, etc., which sometimes occur without being connected with any obvious disease, as in the so-called idiopathic anæmia described by Addison, and which are sometimes superadded to various diseases, may be due to morbid conditions seated in the gastric tubules. Further explorations in this new field of research may lead to developments of as much pathological importance as those which have resulted, within the past few years, from the study of the morbid conditions of the kidney.

The study of the secretory apparatus of the small intestine, or the follicles of Lieberkuhn, may afford a similar field for fruitful research, which as yet appears to have hardly been begun.

The points which it is desirable to settle by a sufficient number of observations are: *First*, the variations in appearances which occur within the limits of health; and the appearances which denote disease, and not cadaveric changes. *Second*, the different kinds of morbid change, together with their pathological character and import. *Third*, the gross appearances corresponding to the changes ascertained by the microscope. *Fourth*, the symptoms associated with different anatomical changes.

The foregoing remarks on degeneration of the gastric tubules were contained in the previous editions of this work, and are retained in this (4th) edition without alteration. Further reflection has served to strengthen, in my own mind, the conviction that important results may be expected from histological researches in this direction. For a long time it has seemed to me a rational supposition that lesions compromising the secretory function of the gastro-intestinal tubules exist in a class of cases characterized by progressive and fatal inanition taking place without the evidence of disease existing elsewhere sufficiently to explain the symptoms and the termination. In an essay written since the publication of the last (3d) edition of this work, I have given abstracts of several cases of this kind which have fallen under my observation.[1] These cases represent a class with which all practising physicians of much experience are more or

[1] The Pathological relations of the gastric and intestinal tubules, by Austin Flint, M.D., New York Med. Journal, March, 1871.

less familiar. The marked characteristics are gradual and, at length, complete loss of appetite and digestive power, with progressive debility, and death by exhaustion, adequate morbid conditions seated elsewhere than in the glands of the alimentary canal being excluded by an investigation of the symptoms and signs. In the cases cited in the essay just referred to, the patients were somewhat advanced in years, and they were healthy prior to the illness which ended fatally; this illness was developed imperceptibly and advanced slowly; the persons were singularly exempt from apparent morbific influences, being temperate and their habits of life regular; they were in easy circumstances, and in a great measure withdrawn from active occupation; the intellectual faculties remained intact up to a few hours before death, and the mode of dying was typical of slow asthenia. The impairment of appetite was the first symptom.

My object in the essay was to show, from a clinical point of view, *first*, the existence of a well-defined class of cases characterized by anorexia, impaired digestion, progressive debility and death from inanition; and, *second*, in view of these clinical characteristics, together with the absence of adequate lesions elsewhere, the probability that the essential disease is seated in the secretory glands of the alimentary canal.

In order that, in this class of cases, lesions of these glands shall be recognized as an established fact, the existence of the lesions must, of course, be demonstrated by microscopical examinations after death. This appears to have been done in a case reported by Dr. Samuel Fenwick,[1] in which the diagnosis of disease of the gastric tubules was made from the symptoms and history. In this case the existence of distinctive lesions here was verified by the microscope, and by estimates showing notably deficiency of the gastric juice. Probably, the whole extent of the pathological relations of the gastro-intestinal tubules is by no means embraced by supposing that the anatomical characteristics in the cases just referred to, are to be sought for in these glands. There are grounds for the belief that lesions here seated are often associated with various diseases, and that functional disorder of these glands enters more largely into morbid phenomena than has hitherto been supposed.

From the histological researches of Jones, Fenwick, and Fox, lesions affecting the secretory function of the tubules correspond with those which occur in other glandular organs, *e. g.*, the kidneys. The point of departure in some cases is within the tubules, the secretory cells undergoing granular fatty metamorphosis, and, finally, disappearing. In other cases, the primary seat appears to be in the connective tissue surrounding the tubules, the latter becoming atrophied by pressure, as in cases of cirrhosis of the kidneys.

[1] *Vide* London Lancet, July 16, 1870. I have quoted the case in full in my essay.

CHAPTER IV.

Structural Affections of the Intestinal Canal involving Obstruction—Invagination—Strangulated Hernia within the Abdomen—Rotation or twisting of Intestine—Compression and Stricture of Intestine. Obstruction from Impaction of Feces, Enterolithes, and Foreign Bodies. Functional Obstruction.

STRUCTURAL affections of the intestines are important, measurably or chiefly as giving rise to obstipation due to mechanical obstruction to the passage of the intestinal contents. Hence we may consider these affections under the head of obstruction of the bowels. And, having considered the important structural affections involving obstruction, it will be convenient to consider, in this chapter, obstipation (meaning by this term obstruction as distinguished from constipation) dependent on causes other than lesions of structure, viz., on the impaction of feces, the formation of concretions called enterolithes, the introduction of foreign bodies, and on merely functional disorder. The term ileus or iliac passion, and other names, have been applied to cases of obstipation with the ejection from the mouth of the intestinal contents, or so-called stercoraceous vomiting. As the latter symptom occurs in connection with obstruction from various causes, the names based upon it have no special pathological significance and tend to produce confusion.

Obstruction from structural affections is happily not of frequent occurrence. According to the statistical resources of Benjamin Phillips, it is met with in a proportion of one per cent. in post-mortem examinations.[1] Similar researches by Brinton, the whole number of promiscuous necropsies being 12,000, showed obstructions from various causes, exclusive of hernia, in the proportion of 1 in 280 deaths.[2] The lesions involving obstruction are the following: Intussusception, invagination or volvulus; strangulation from hernia within the abdomen; rotation of a portion of intestine upon its own axis, or upon the mesentery, and, according to Rokitansky, twisting of a portion of intestine around another coil of intestine; compression of one portion of intestine by another portion, or by a tumor situated exterior to the canal, and stricture produced by morbid growth within the canal or by the contraction following the cicatrization of ulcers. The symptoms attending these several affections are not, in all respects, the same, although obstipation is a common feature. They will therefore claim separate consideration. But it will be seen that it is not always easy to determine, by means of the symptoms in individual cases, the particular lesion which occasions the obstruction.

INVAGINATION.

Invagination, intussusception, or volvulus, is the reception of a portion of the intestines into another portion. Generally the invagination is from above downward, but sometimes the lower portion is received into the upper. The latter, called retrograde invagination, was found in 3 of 59 cases ana-

[1] Trans. Royal Med. and Surg. Society of London, vol. xiii. 1848.
[2] British and Foreign Medico-Chirurg. Review, October, 1867.

lyzed by Dr. S. Foster Haven.[1] It is certain that invagination may occur transiently, giving rise to no symptoms. In post-mortem examinations, especially in children, innocuous invaginations of the small intestine are not infrequently found; the invaginated portion is restored without difficulty, and, aside from the displacement, there are no morbid appearances. In such instances, they have probably occurred in the last moments of life. I counted as many as fifteen of such invaginations in the body of a child dead with typhoid fever. It is not unlikely that they occur frequently in connection with various diseases and even in health. It is only when the invagination becomes fixed, giving rise to congestion, inflammation, etc., that it occasions obstruction and other symptoms. It is then a lesion of very great gravity, in the great majority of cases ending fatally. This is the most frequent of the lesions causing fatal obstruction. Of 169 cases of obstruction from various lesions collected by Phillips, 63 were of this class. An analysis of 600 cases by Brinton showed in 43 per cent. the obstruction to be from intussusception.

Invagination brings into apposition three layers of intestine, viz., an entering, a returning, and a receiving layer. In the relation of the entering and receiving layer, mucous surfaces are in contact, and these do not become adherent. But serous surfaces are in contact in the relation of the entering and returning layer, and inflammation, excited at the point of entrance, leads to adhesion of these surfaces, extending more or less beyond the point of entrance. In this way the invagination becomes fixed. The vessels of the portion of the mesentery connected with the invaginated intestine are obstructed by tension. Congestion and swelling of the invaginated intestine ensue, and, at length, it becomes gangrenous, as if strangulated, and sloughs away, if life be sufficiently prolonged. The obstruction is due to the swelling from congestion and the exudation of lymph. Usually the obstruction is complete, but exceptional cases have been reported in which the intestinal passage remained pervious but much contracted. Peritonitis is apt to extend more or less around the seat of the invagination, leading to morbid attachment to the adjacent parts.

The invagination may occur at any point in the intestinal tract. Its most frequent seat is at the junction of the ileum and cæcum. This is shown in cases of children, by the valuable statistical researches of Dr. J. Lewis Smith.[2] Dr. Smith's account of the mode in which it generally occurs is as follows: "The intussusception not infrequently begins in the prolapse of the ileum through the ileo-cæcal valve, in the same way that prolapse of the rectum occurs through the sphincter ani. If death take place early, only a small portion of the ileum may have passed the valve. If the case be protracted, the tenesmus brings down more and more of the ileum with its accompanying mesentery. The constriction of the valve, which acts as a ligature, prevents the further descent of the ileum, and, the tenesmus continuing, the next step is the inversion of the caput coli, which is drawn into the colon by the descending mass; and unless the case terminate by sloughing or death, the ascending and transverse portions of the colon are successively invaginated. Not infrequently, the cæcum is the part primarily inverted and invaginated, and, descending along the colon, it draws after it the ileum which sustains its natural re-

[1] American Journal of Med. Sciences, October, 1855.

[2] Statistical Researches relative to the Seat, Symptoms, Pathological Anatomy, etc., of Intussusception in Children. Am. Jour. of Med. Sciences, Jan. 1862. *Vide*, also, Smith on the Diseases of Children, second edition, 1872.

lation to the ileo-cæcal valve. These two forms of invagination—that in which the ileum, passing through the ileo-cæcal valve, successively inverts and draws after it the caput coli and the divisions of the colon, and that in which the caput coli is primarily invaginated, and, descending along the large intestine, inverts the latter, and draws after it the ileum—constitute the vast majority of cases of this disease in childhood." The invaginated portion may descend so low as to be felt and seen at the anus, and it may even protrude from the body. It is, however, to be borne in mind that the invagination may occur at any point in either the large or small intestine. In Dr. Haven's analysis of 59 cases it was seated in the small intestine in 23. Of the cases analyzed by Brinton, the intussusception was ileo-cæcal in 56 per cent.; iliac in 28 per cent.; jejunal in 4 per cent., and in the colon in 12 per cent.

Invagination causing obstruction, as already stated, proves fatal in the great majority of cases; yet the affection is by no means absolutely hopeless. The manner in which recovery usually takes place is of importance in its bearing on the treatment. The invaginated portion of intestine sloughs away and is evacuated, the entering and receiving portion at the point of entrance remaining adherent, and the perviousness of the canal being restored. Cases have been reported in which a large portion of invaginated intestine was thrown off, and recovery followed. Prof. Van Buren reported a case to the New York Pathological Society, in which five feet of intestine were passed *per anum*, the patient recovering. Prof. Peaslee exhibited at a meeting of the New York Academy of Medicine, 1865, five feet of intestine which had been passed *per anum* four months before the death of the patient. He also exhibited the intestines removed from the body of this patient after death. The small intestine was only 16 feet in length, the length of the large intestine being 5 feet and 10 inches. The invagination and sloughing had taken place in the small intestine at a distance of six feet from the duodenum. A stricture existed at this point; the intestine above was much dilated, and that below greatly reduced in size. The patient died from inanition dependent on the stricture of the intestine.[1] Dr. William Thompson, of Edinburgh, collected 43 cases ending in recovery.[2] Of Dr. Haven's 59 cases, in 12 the invaginated portion was passed per anum, and of these 12 cases 10 ended in recovery. This is the mode of recovery which is to be hoped for after permanent incarceration of the invaginated intestine has taken place.

The prominent local symptoms which enter into the clinical history of invagination are as follows: Pain is more or less prominent, at first paroxysmal as in colic, and after a time becoming constant, with frequent exacerbations. The pain, if the patient be old enough to describe it, appears to emanate from a certain fixed point. Tenderness at first may not be marked, but becomes developed, being either limited to, or greatest at, the point whence the pain emanates. The tenderness and constant pain denote the occurrence of peritonitis at the seat of the invagination. Vomiting soon becomes a prominent and persisting symptom, with very few exceptions. The vomited matter, after a time, may have the odor of feces, and is then said to be stercoraceous. A truly stercoraceous vomiting, however, very rarely, if ever, takes place—that is, the contents of the large intestine are not ejected. This could, of course, only happen when the obstruction commences below the cæcum, which is extremely rare;

[1] *Vide* Bulletin of the New York Academy of Medicine, vol. ii., Nos. 25–29.

[2] *Vide* article on Internal Strangulated Intestine, by Elisha Harris, M. D., in New York Journal of Medicine, 1853.

but, even if the cæcum be above the seat of the invagination, the ileo-cæcal valve, certainly in the great majority of cases, effectually prevents regurgitation of the contents of the large into the small intestine. Experiments and clinical observation show that the ileo-cæcal valve will sustain an amount of pressure sufficient to cause rupture of the intestinal walls. It is not, however, improbable, as has been conjectured, that regurgitation may sometimes take place to some extent, provided the ileum as well as the cæcum at the point of junction be distended. The accumulation of ingesta and gas above the obstruction occasions more or less abdominal distension, provided the invagination be not situated in the upper portion of the small intestine. Frequently the accumulation of intestinal contents at the seat of the invagination gives rise to a tumor appreciable by the eye and touch, and to dulness on percussion. After the contents of the intestinal canal below the point of obstruction have been evacuated, there is persisting obstipation, save in a very few exceptional cases. If the invaginated portion of intestine descend to the rectum, tenesmus is felt, and the patient is led to make straining efforts. Under these circumstances bloody mucus is expelled, as in dysentery.

The general symptoms at first may not be marked, but soon they denote a grave affection. The pulse becomes accelerated, its frequency progressively increases and it is proportionally feeble or compressible. Progressive prostration, hiccough, coolness or coldness of the surface, an anxious or haggard expression, denote the progress toward a fatal termination. The mode of dying is by asthenia, the pain and tenderness frequently diminishing or ceasing for some time before death.

A favorable progress is denoted by the occurrence of free evacuations from the bowels, the discharge of the invaginated portion of intestine, together with improvement in all the local and in the general symptoms.

Invagination is to be discriminated from functional colic, acute peritonitis, and obstruction from other causes. The symptoms at first may denote nothing more than colic. The persistency of pain, the development of tenderness, the acceleration of the pulse, the vomiting, etc., however, soon point to an affection of greater gravity than colic. Acute peritonitis is to be excluded by the gradual development of the local and general symptoms; by the absence of diffused tenderness over the abdomen, and of rigidity of the abdominal muscles; by the localization of pain and tenderness within a circumscribed space, and by the signs of a tumor in some cases. Acute peritonitis sometimes supervenes, in cases of invagination, from rupture of the intestine above the obstruction. From obstruction caused by hernia within the abdomen, and rotation and twisting of the intestine, the discrimination is more difficult, and, indeed, cannot always be made with positiveness. The age of the patient has a bearing on the diagnosis. Invagination occurs most frequently in infancy. According to Dr. Smith's statistics, it is most apt to occur between the second and third month of infantile life. Of 47 cases only 18 occurred between the ages of one year and twelve years. In Dr. Haven's cases the mean age was 18 years; the youngest age was 3 months, and the oldest 65 years. Male children, more than female, are liable to it, the relative proportion, in Dr. Smith's cases, being thirty-two to twenty-two, and in Dr. Haven's 59 cases 34 were males. On the other hand, hernial obstruction occurs oftener after infancy and childhood, and cases occur oftener in females than in males. The discharge of blood and mucus is distinctive of invagination involving the large intestine.

A point in diagnosis is to determine the probable seat of the invagination. The chances are that it is seated at the junction of the large and

small intestine. The probability of this being the seat is increased, if the pain, tenderness, and swelling are situated in the neighborhood of the right iliac fossa. Tenesmus, with the discharge of blood and mucus, shows that the large intestine is involved. The invaginated portion may sometimes be felt and seen within the rectum. If seated in the small intestine, the constitutional disturbance is greater, and, if the point of obstruction be toward the upper portion of the small intestine, there will be little or no abdominal distension. Barlow considers the quantity of urine as furnishing a guide to the situation of the obstruction. If the small intestine be unobstructed, liquids ingested are abundantly absorbed, and the urine is proportionately abundant, but if the obstruction be situated high up in the small intestine, the diminished absorbing surface involves a scanty secretion of urine.[1] It is doubtful if much reliance is to be placed on this test.

The prognosis is extremely unfavorable. The usual mode of recovery in the exceptional cases in which the affection does not end fatally, has been stated, viz., by sloughing away of the invaginated portion of intestine, the adhesions at the point of entrance being permanent. It is possible that the invaginated portion may be restored, in some cases, after symptoms denoting the affection are developed, but such instances must be exceedingly rare. And it must be equally rare for the invaginated portion of intestine to remain, the canal becoming or continuing pervious. Of the 50 cases analyzed by Dr. Smith, in 7 recovery took place, and in each case by sloughing. In all these 7 cases the ages were between 5 and 12 years, Dr. Smith's researches being limited to cases occurring in childhood. The constitutional powers in infancy do not seem to be adequate to support the affection for a sufficient period for the sloughing process to be completed. The separation of the invaginated portion of intestine takes place between the sixth and twelfth day. In fatal cases, the duration rarely extends beyond eight days. Death may take place within twenty-four hours. In the majority of cases, life is not prolonged beyond the third day. Dr. Smith cites a case in which the symptoms of invagination had existed for six weeks, and in another case, for three months before death, the obstruction in both cases not being complete, and the invaginated portion of intestine not completely strangulated. Death sometimes is hastened by peritonitis caused by rupture of the intestine above the seat of the obstruction. In young children the duration is sometimes shortened by the occurrence of convulsions. Generally the mode of dying is by slow asthenia.

If the existence of invagination could be ascertained prior to the development of symptoms denoting incarceration, it is probable that measures for restoration might be successfully employed. But generally a day or two elapses before the character of the affection is even suspected. In the mean time, cathartics will be likely to increase the invagination and diminish the practicability of restoration. The liability to the existence of this affection, especially in children, should be borne in mind in cases of apparent colic, and should dictate reserve in the employment of cathartics. So soon as the character of the affection is rendered probable by the symptoms, measures to effect restoration may be tried. These measures are the injection of water or of air in considerable quantity into the rectum. If practicable, the injection should be made through a long flexible tube carried into the intestine as far as it can be made to pass without undue force. The object is to effect the restoration by the upward pressure of

[1] Practice of Medicine.

the air or water, the invagination being, in the great majority of cases, in a downward direction. The injections are not to be pushed beyond the point at which they are borne without much suffering, and, if they do not succeed after a fair trial, they are not to be persisted in. They will very rarely succeed after the invaginated portion of intestine has become swollen by congestion and the peritoneal surfaces in contact have become adherent. If pushed too far, rupture of the intestine below the seat of the obstruction may be produced. I have known rupture to result from the injection successively of an acid and alkaline liquid, giving rise to the evolution of gas by combination within the intestine. This method of employing pressure is highly objectionable, because the amount of pressure cannot be regulated. Cases have been repeatedly reported in which the injection of air or water has apparently effected restoration in cases of supposed invagination, even after obstruction had existed for several days. But it is probable that in a certain proportion of these cases invagination did not really exist. These measures for reduction are of no avail if the seat of the invagination be above the ileo-cæcal valve.

Exclusive of measures for reduction, the objects of treatment are to secure as much quietude of the intestinal canal as possible, to palliate suffering, and support the powers of life, under the hope that sloughing and recovery may take place. The avoidance of cathartics is essential. The practitioner is not to be tempted to employ them with the hope of overcoming the obstruction. They interfere with the objects just named, and are destructive. Not only the active cathartics, but even mild purgatives and laxatives are contra-indicated. To quiet the peristaltic movements, opium is to be given in sufficient doses to secure relief of pain without inducing narcotism. Fomentations over the abdomen are useful. The strength of the patient is to be supported by concentrated and purely nutritious food given in small quantities at a time, together with alcoholic stimulants. It is to be borne in mind that the recovery will depend on life being sufficiently prolonged for the sloughing away of the invaginated portion of intestine. Bloodletting, counter-irritation, or any measures which tend to impair the vital forces, are never indicated, and cannot fail to do harm. After sloughing has taken place and the obstruction is removed, purgatives are not to be employed, lest, by exciting unduly peristaltic movements, the adhesions at the point of the invagination may be broken up and peritonitis ensue from the escape of the contents of the intestine into the peritoneal sac.

Gastrotomy has been resorted to as a last resource in cases of invagination. Phillips collected 27 cases in which this operation was performed, and in 2 of these cases it proved successful. One was the case of a negro reported by Dr. Wilson, in the *American Journal of Medicine*, vol. x. The first object of the operation is to restore the parts if practicable, and a second object to perform enterotomy and establish an artificial anus. Life may be prolonged if the latter object be accomplished, although recovery does not take place. The chances for restoration would be greater in proportion as the operation was resorted to early, but few surgeons would be willing to make so formidable an operation at a period when the diagnosis might hardly be considered as settled. After strangulation has existed for some time, it would not be advisable to restore the parts even were it practicable. In short, at the time when the operation, if employed at all, would be advisable, the chances of recovery after it would be less than if reliance were placed on a spontaneous cure. Even with a view to artificial anus, the operation would be likely to lessen the chances of a

spontaneous cure. The propriety of surgical interference has therefore justly not many advocates.

STRANGULATED HERNIA WITHIN THE ABDOMEN. ROTATION OR TWISTING OF INTESTINE.

Several abnormal conditions lead to hernia within the abdomen. Fissures sometimes exist in the mesentery, omentum, and diaphragm, into which a portion of intestine passes and is liable to become incarcerated and strangulated. The vermiform appendix of the cæcum sometimes becomes adherent to an adjacent part, leaving a loop through which intestine may pass and become ligated. The same may happen in connection with diverticula of the intestinal tube, which are not very infrequent. Bands of adventitious membrane, resulting from peritonitis, may leave spaces for hernial protrusions. Whatever be the mode in which the strangulation is produced, the symptoms are the same. They are, in fact, identical with the symptoms of ordinary strangulated hernia occurring at the femoral or the inguinal outlet, and they are, for the most part, the same as in cases of invagination. The existence of tenesmus with bloody and mucous evacuations, in certain cases of the latter, constitute the chief point of distinction. Irrespective of the symptoms just named, the differential diagnosis can hardly be made with positiveness, but the chances are that in the young child invagination exists, whereas, in after life, obstruction from other causes is more liable to occur. The small intestine is far more likely to be the seat of hernia within the abdomen than the large intestine. Sloughing of the strangulated portion of the intestine is destructive, whereas, in cases of invagination, it is the mode of cure. The only hope of recovery is in the spontaneous reduction of the hernia, before gangrene takes place. The practitioner can do nothing directly towards reduction. Distending the large intestine with air or water will be useless if the seat of the hernia be in the small intestine. Cathartics in these cases are more likely to do harm than good. Opiates to palliate pain, fomentations to the abdomen, and supporting measures constitute the appropriate treatment. The prognosis is as unfavorable as possible.

Rotation or twisting of a portion of intestine, so as to induce strangulation, is most apt to occur at the sigmoid flexure of the colon. Rotation of the sigmoid flexure twice upon itself, causing fatal obstruction, occurred in the person of a distinguished member of the cabinet of the United States many years ago.[1] Habershon gives a case in which the rotation occurred at the cæcum, this portion of the large intestine being unusually mobile. Twisting of a portion of intestine round an axis formed of mesentery, or around another coil of intestine, occurs in the small intestine. These accidents are happily to be reckoned among the rare curiosities of clinical experience. Their symptoms are those of strangulation, and it is impossible to discriminate them from invagination or hernia within the abdomen. In the analysis of 600 fatal cases of obstruction from various causes, exclusive of hernia, rotation or twisting of intestine occurred in 8 per cent.

A highly important injunction is to be added to the consideration of obstruction dependent on the foregoing structural affections. It is for the practitioner, in all cases which present the symptoms of these affections, to examine carefully for inguinal or femoral hernia. The hernial

[1] Hugh S. Legaré. Case reported by Prof. Jacob Bigelow, Am. Jour. of Med. Sciences (new series), vol. vii., 1843.

tumor may be so small as not to excite the attention of the patient, and, in females, motives of delicacy may prevent the patient from suggesting an examination, even when the presence of a tumor is known to her. Instances have repeatedly occurred of patients dying with strangulated femoral or inguinal hernia which was overlooked, the symptoms being attributed to some inaccessible lesion, or even to functional disorder.

COMPRESSION AND STRICTURE OF INTESTINE.

Obstruction due to closure or diminished calibre of the intestinal tube by morbid growths within the tube, the pressure of tumors situated exterior to the tube, or constriction following the cicatrization of ulcers, differs from obstruction caused by the structural affections already noticed, in not involving strangulation. The obstruction, under these circumstances, is developed gradually, having been preceded by progressively increasing constipation. The obstruction is rarely complete. The local and constitutional symptoms incident to sphacelation and sloughing of the intestine are wanting. The symptoms are those arising from the gradual accumulation of the contents of the intestine above the point of obstruction. The affection progresses more slowly toward a fatal termination, after the obstruction becomes nearly or quite complete.

Cases of obstruction falling under this head form a considerable proportion of the cases of obstruction from all causes. In an analysis of 127 cases, including cases of obstruction from fecal accumulation and functional disorder as well as structural lesions, by George Pollock, 77 were of this class.[1] And in the great majority of the cases of this class, the seat of the obstruction is in the lower part of the large intestine. Of the 77 cases just referred to, in 60 the seat was either at the sigmoid flexure of the colon or in the rectum. In about one-half of these 77 cases the obstruction was due to cancer. Cancer is much more infrequently seated in the intestinal canal than in the stomach. It is oftener seated in the large than in the small intestine, and the portions of the large intestine in which it is most apt to be seated are the rectum and the sigmoid flexure of the colon.

The discrimination of the cases of obstruction caused by compression or stricture from the cases involving strangulation can generally be made, clinically, by means of the differential points which have just been stated.

The fact of the obstruction being seated in the lower part of the large intestine can generally be ascertained. If seated in the rectum, it is accessible to direct exploration. If seated at the sigmoid flexure, the fact is shown by the evidence, afforded by manual exploration, of distension of the transverse and ascending colon, and by the inability to inject liquid beyond the rectum. *Per contra*, the situation at the upper part of the large intestine or in the small intestine is shown by the absence of distension of the large intestine with intestinal contents, and by the inability to fill the colon with injected liquid. The obstruction may be complete, but, in general, a certain quantity of liquefied fecal matter passes the point of obstruction and is evacuated.

The distension from accumulation of the intestinal contents may lead to rupture of the intestine. And the distension may gradually go on and lead to this accident without sufficient pain or other symptoms to direct attention to the existence of any serious obstruction. This fact was illustrated by a case under my observation at Bellevue Hospital, in which

[1] *Vide* Medico-Chirurg. Review, 1853, vol. xii. p. 243.

nothing more than ordinary constipation had been suspected, when peritonitis suddenly became developed, ending fatally in a short time. Obstruction was produced in this case by a cancerous tumor at the sigmoid flexure; the colon and cæcum were enormously distended with feces, and the peritonitis was due to rupture of the cæcum. This case illustrates the ability of the ileo-cæcal valve to resist an amount of pressure sufficient to lead to rupture of the cæcal walls.

In the treatment of obstruction from compression or stricture, active purgatives are to be avoided, but the trial of saline laxatives in small doses, in order to liquefy the intestinal contents, is admissible. Colic pains are to be relieved by opiates. The diet should be nutritious and concentrated, in order to leave as little fecal residue as possible. If the obstruction be situated at the lower part of the large intestine, careful efforts to pass a flexible tube beyond the constricted portion may be employed, and, if successful, liquid may be injected above the obstruction.

In cases of obstruction from compression or stricture at the lower part of the large intestine, enterotomy with a view to the establishment of an artificial anus is warrantable, provided other measures to free the intestine from an amount of an accumulation likely to lead to rupture be not successful. Cases have been reported in which life has been prolonged and comfortable health obtained by means of surgical interference.[1] Cæsar Hawkins reported the results of the operation for artificial anus in 44 cases.[2] In 10 of these cases death took place within 48 hours, in 21 within five weeks, and in 13 the operation was successful. Of these 13 cases, 6 died in six months, and 7 survived more than a year.

OBSTRUCTION FROM IMPACTION OF FECES, ENTEROLITHES, AND FOREIGN BODIES.

Obstipation may be produced by the causes named in the above heading, but in general they induce only more or less constipation, and, in treating of the latter affection, they will again be referred to. An accumulation of a mass or of masses of hardened feces, sufficient to produce obstruction, may take place in different parts of the large intestine. The rectum in aged persons not infrequently is the seat of such an accumulation. It is to be suspected when enemas cannot be given, and perhaps the pipe of the syringe is found to penetrate a fecal mass. Examination shows the seat and the character of the obstruction. It may be necessary to break down and remove the accumulation by a scoop or the handle of a spoon. The accumulation may be at the sigmoid flexure, and then resistance to the passage of liquid injected and to the introduction of a flexible tube is found to be at that point. The accumulation may be at any point above the sigmoid flexure, but it is oftenest in the cæcum or ascending colon.

Masses of feces above the sigmoid flexure may give rise to a tumor or to tumors appreciable by manual exploration through the abdominal walls. These fecal tumors are liable to be mistaken for others of a different character. A female in the country presented an abdominal tumor of the character of which her attending physician was not satisfied, and an eminent professor of anatomy, now deceased, was requested to see the case. He was led to regard the tumor as malignant, and, of course, to form a very unfavorable prognosis. Shortly after the consultation a profuse

[1] For a striking case, see Medico-Chirurg. Trans. of Royal Med. and Surg. Society of London, vol. x. 2d series, 1845.

[2] *See ibid.*, vol. xxxv., quoted in Habershon's work.

diarrhœa set in, and, much to the astonishment of the patient and her physician, the tumor suddenly disappeared. It was a fecal tumor. In view of the liability to error of diagnosis, and in order that appropriate measures of treatment may be pursued, the distinctive features of these tumors are to be borne in mind. One point in the diagnosis is their situation in the tract of the colon. They are not tender on pressure, but may be handled freely without giving pain. By firm and continued pressure, perhaps, they may be moved backward or forward in the direction of the colon. By firm and continued pressure, also, the form of the tumor may be altered.

The absence of pain, tenderness, vomiting, and the constitutional symptoms accompanying invagination, internal hernia, and twisting of the intestine, suffices to exclude these affections; but it cannot be at once determined that the obstruction is not due to compression or stricture. The effect of measures of treatment will be likely to settle the diagnosis. The measures to be employed are purgatives, especially salines, and stimulating enemas. The latter will be more effective if administered through a long flexible tube introduced into the bowels. These measures, judiciously employed, will generally prove successful, without much delay, in relieving the obstipation and causing the fecal tumors to disappear. Mild purgatives may be required for some time after the obstruction is removed; the treatment, then, will resolve itself into that adapted to habitual constipation.

Obstruction may be due to the presence of intestinal concretions, or enterolithes. These are composed of different substances, such as magnesia or the sesquioxide of iron taken as a remedy, the husk of oatmeal in countries in which this article of food is largely used, cholesterine, the flour of sulphur, cubebs, white mustard-seed, chalk, etc. The seeds or stones of fruit and other indigestible constituents of food may form a conglomerate mass of sufficient size to give rise to obstipation. In a case related to me by Dr. Sands, of Newport, R. I., obstipation resulted from an accumulation of grape seeds, the patient having eaten, for the space of three months, two or three pounds of grapes daily; the patient, for several weeks, discharged grape seeds at his stools, and, also, with flatus. I have known a smooth, oval body, as large as a hen's egg, to be passed from the bowels, which appeared to be composed of pure cholesterine. A gall-stone, or some solid body contained in the aliment, may serve as a nucleus on which earthy matter in the intestinal contents is deposited, forming a concretion of greater or less size. These obstructing bodies may be situated within the cæcum, at the sigmoid flexure, or in the rectum. They may sometimes be felt through the abdominal walls. The nature of the obstruction in these cases can be determined only after the concretions have been evacuated, or by means of a post-mortem examination. They may lead to ulceration and perforation of the intestine, or, if not discharged and the obstruction be complete, vomiting of so-called stercoraceous matter ensues, and death may take place from exhaustion.[1] An intestinal concretion, cuboid in form, the vertical and transverse diameter one and a half inches, its weight fifteen drachms, was sent to me by Dr. O. T. Jameson, of South Otselic, Chenango County, New York, with a report of the case, which I communicated to the New York Pathological Society, February, 1867. This concretion was found after

[1] For statistical details relating to the different lesions occasioning obstruction, *vide* Dr. Haven's article, before referred to. The article gives the results of the analysis of 258 cases.

death in the ileum just above the cæcum. It was distinctly felt through the abdominal walls during life, and had existed for over twenty years. The patient was a shoemaker, and experienced notable inconvenience from the concretion only at times after overwork, or after violent muscular exertion. He died of pneumonia, at the age of 47. Portions of the concretion were examined for cholesterine with a negative result; the composition appeared to be fecal.

Finally, foreign bodies, that is, by way of distinction, bodies not contained in the aliment nor derived from the body, may pass into the intestinal canal from the stomach, or be introduced into the rectum. In the latter case their presence is readily ascertained by exploration, and they are removed by appropriate surgical appliances. When introduced into the stomach, they have been swallowed either deliberately, as is done by jugglers, or inadvertently. Prof. Gross, in his comprehensive work on Surgery, cites the case of a man in Iowa, who swallowed a bar of lead weighing a pound, which was removed from the stomach by an opening made through the abdominal walls, and the patient recovered. The same author refers to another case in which a large teaspoon was swallowed in a fit of delirium, and this was extracted from the ileum by the operation of enterotomy.[1]

Foreign bodies, not sufficient in number, or not large enough, to occasion obstruction, are often swallowed, especially by children. The practitioner is frequently summoned in haste, and great anxiety is felt when bodies such as pins, coins, portions of glass, etc., are known to have been swallowed. They may give rise to more or less irritation of the mucous membrane; they may even occasion ulceration and perforation of the stomach or intestines. In general, however, they pass through the alimentary canal without any appreciable inconvenience; and the physician is warranted in giving assurances of the absence of danger. It is not judicious, in such cases, to give cathartics or laxatives. The mucous membrane is best protected against injury, if a sharp-pointed or irritating body be contained in the solid contents of the bowels. Moreover, the increased peristaltic movements caused by a purgative increase the risk of injury. The desire to have anxiety relieved as quickly as possible, by ascertaining that the foreign body has passed, is an inducement to resort to purgation, which is to be resisted.

FUNCTIONAL OBSTRUCTION.

Persisting obstipation accompanied with vomiting of so-called stercoraceous matter, colic pains, etc., may occur, there is reason to believe, as a purely functional disorder, constituting an affection which has been called *idiopathic ileus*. A person is seized with abdominal pain, increased paroxysmally; vomiting soon takes place, and, after a time, the matter vomited has the odor of feces; measures to procure evacuations from the bowels are ineffectual, the pulse becomes frequent, and there is more or less prostration. After the lapse of a week or more, these symptoms subside, free evacuations from the bowels ensue, and the patient recovers. These are the prominent features of a case which I reported some years ago.[2] The patient was a female, aged twenty-five; hysterical symptoms

[1] For a collection of cases of foreign bodies in the stomach and the intestines, by Alfred Poland, *vide* Guy's Hospital Reports, vol. ix. p. 1063.

[2] Buffalo Med. Journal, vii. p. 530, 1851.

were associated; the treatment consisted of the free use of opiates, and enemas administered through the long flexible tube. In this case, the patient declared that she tasted castor-oil which was given exclusively per enema, and it was said that oil was observed to float on the matters vomited. Cases have been reported in which diverse substances injected into the rectum were supposed to be ejected from the stomach. In most of such instances the accuracy of the observation may fairly be questioned, and I do not suppose that in the case reported by me the oil passed above the ileo-cæcal valve. The taste of oil may have been real, and may be explained on the supposition that enough was absorbed from the large intestine to be appreciated by the gustatory nerve.

Dr. S. B. Hunt subsequently reported a case in which obstipation existed for fifteen days, and during this period the patient vomited matter described as "horribly fetid and stercoraceous." This case was treated for the first five days by giving active cathartics. At the end of this time the condition was so unpromising that the cathartics were discontinued and a soothing treatment adopted with a view to euthanasia. Under the latter treatment the symptoms denoted gradual improvement, evacuations from the bowels occurred spontaneously, and recovery took place. This patient was a female, aged thirty-five, and a sufferer from symptoms connected with spinal irritation.[1]

Such cases simulate those of obstruction from the structural affections which have been considered, and there is ground for the belief that in a certain proportion of the reported cases of the successful treatment of invagination or strangulated hernia within the abdomen, the affection was purely functional. The regurgitation of the contents of the small intestine, which have a stercoraceous odor from the diffusion of the gases contained in the large intestine, in these as in other cases of obstruction, is generally attributed to an inversion of the peristaltic movement. Brinton explains it by supposing that in the centre of the intestinal tube a retrograde current is produced by the normal peristaltic movements, if there be an obstruction. The obstruction, when functional, may be caused by spasmodic contraction of the tube, or it may be due to paralysis of a portion of the tube, and consequent failure of this portion to propel its contents.

The clinical discrimination of functional obstipation from obstruction caused by structural affections, cannot always be made at once with confidence. The absence of tumor and of pain and tenderness localized at a particular point, tends to the exclusion of the latter. The functional character of the affection may be surmised if the patient be a female subject to hysteria, and suffering from the nervous symptoms associated with so-called spinal irritation. The probability of the affection being functional is increased in proportion as the obstipation, with vomiting, etc., continues, without the supervention of the symptoms which occur after sphacelation of intestine has taken place, viz., frequency and feebleness of the pulse, coldness of the surface, extreme prostration, great tympanites, in short, the symptoms denoting impending death by asthenia.

In the treatment of functional obstipation, opium and other measures to relieve pain and allay spasmodic action are indicated. Cathartics may be cautiously tried, but, if ineffectual, should not be persisted in. Enemas administered by means of a long flexible tube are to be employed.

The importance of examining for the evidence of femoral and inguinal hernia is to be enforced in connection with the subject of functional obstipation.

CHAPTER V.

Functional Affections of the Stomach and Intestines—Dyspepsia—Polyphagia, Malacia or Pica, Polydipsia, Dipsomania. Gastrorrhagia.

OF the functional disorders of the stomach and intestines, a large proportion relate to digestion, that is, to the processes involved in the changes which the ingesta undergo prior to the function of absorption. The processes of digestion take place chiefly within the stomach and small intestine. Clinical observation shows, it is true, that, under certain circumstances, aliment introduced into the large intestine is digested. But it would appear that digestion in the large intestine is performed vicariously, and hence, disorders of this function are hardly applicable to this portion of the alimentary canal. The greater part of the functional disorders of digestion are commonly embraced under the name *dyspepsia*. This name signifies simply difficulty of digestion, but, conventionally, it is applied to cases in which the digestive processes are disturbed in various ways, as well as to the cases in which their performance appears only to be difficult. Generally, dyspepsia denotes ailments which are sufficiently persisting to be considered as chronic. The term *acute dyspepsia*, however, is applied to disorder of the digestive organs, attended with comparatively violent symptoms, and having a short duration. The disorder so called claims a brief notice.

The term acute dyspepsia denotes an affection called by French writers *embarras gastrique*, and popularly known with us as a *bilious attack*. When accompanied with more or less febrile movement, it is sometimes called *gastric fever*. The latter term is objectionable, because it implies that the affection is essentially a fever, whereas the febrile movement is symptomatic. The term bilious attack is also objectionable, because it is by no means clear that the pathology of the affection involves any special disturbance of the liver. In the absence of precise knowledge of the pathological character of the affection, the term acute dyspepsia is to be preferred, inasmuch as, pathologically, it expresses no more than a functional disorder pertaining to digestion. The term, in fact, is applied to cases embracing, probably, different morbid conditions.

In certain cases of acute dyspepsia, the difficulty is expressed by calling it a fit of indigestion. Gastric disorder is occasioned by over-repletion of the stomach, the ingestion of indigestible articles of food, or an arrest of digestion by strong emotions, fatigue, or other causes. The disorder is manifested by a sense of weight, fulness, or pain in the epigastrium; nausea and perhaps vomiting may occur, or, after a time, looseness of the bowels ensues; some febrile movement may be induced, with pain in the head and general malaise. Succeeding these symptoms are loss of appetite, coating of the tongue, an unpleasant taste, with more or less uneasiness referable to the digestive organs for several days. Such cases are sufficiently common. In the way of treatment, they claim only a mild evacuant remedy, and regulated diet for a few days, with, perhaps, some tonic remedy.

The practitioner meets often with cases which differ from the preceding

in the disorder not being distinctly referable to a fit of indigestion. There is impairment or total loss of appetite; nausea and slight vomiting may occur, but oftener a liquid containing bile is regurgitated; uneasiness or undefined distress is felt in the neighborhood of the stomach; the bowels are sometimes constipated and sometimes loose; the patient complains of a bitter taste, and the breath is frequently offensive; the tongue becomes furred or coated: pain in the frontal region of the head is a frequent symptom, which, if accompanied by nausea, goes by the name *sick headache;* the urine deposits in abundance the lithates; in some cases there is moderate febrile movement; the countenance frequently presents a sallow appearance. These are the symptoms belonging to an affection which may be called acute dyspepsia. Patients imagine that their malady is very clearly defined when they declare that they are bilious. It is frequently, if not generally, difficult to trace the affection to any cause. It occurs undoubtedly oftener in the spring than in other seasons of the year. It continues a few days, and gradually the normal condition of the stomach and system is regained. It is probable that in many, if not most, cases of acute dyspepsia, there is subacute gastritis. In certain cases the affection is that called by some authors catarrh of the stomach, to which reference has been already made.

Patients with acute dyspepsia are apt to desire active treatment. They fancy they need cleansing remedies, and in this light they regard emetics and cathartics; or they solicit medicines to act upon the liver. Readjustment of digestion, etc., takes place without medication, but a mercurial cathartic often appears to afford prompt relief. A few grains of calomel or blue mass, followed by a saline purgative, and, afterward, a mild tonic such as a grain or two of quinia two or three times daily, with regulated diet, are appropriate measures of treatment.

The term *dyspepsia*, without the prefix *acute*, is applied to a more persisting affection than that just considered. As the name of a functional affection, it is not correctly used when applied to disorders of digestion connected with inflammation or structural lesions of the digestive organs, nor to disorders incident to fever and other general diseases. The term is much less frequently used now than formerly. One reason for this is, formerly the term had a wider latitude than now, embracing affections which progress in pathological knowledge has placed nosologically elsewhere. But the affection is undoubtedly less prevalent than it was a quarter of a century ago in this country. Of course, as a functional affection, it has no anatomical characters or morbid anatomy.

The symptoms of dyspepsia are, in the first place, local, that is, referable directly to the stomach or small intestine, and, in the second place, manifested elsewhere, in other words, sympathetic or consecutive. The local symptoms, which will be first noticed, are varied in character, and might serve as a basis for the subdivision of dyspepsia into several varieties.

These symptoms are conveniently classed as follows: *First*, symptoms denoting labored or difficult digestion; and, *second*, symptoms proceeding from imperfect or disturbed digestion.

In certain cases of dyspepsia, the processes of digestion appear to be fully accomplished, but they are accompanied with uncomfortable sensations. In healthy persons, as is well known, a good digestion is productive of a sense of comfort. It is quite the reverse in some dyspeptics. They are often uneasy or miserable while the digestive processes are going on; they complain of uneasiness in the stomach or intestines, of a sense

of distension, and of a general sense of discomfort. And these symptoms may afford the only evidence of disorder. The food appears to be digested, and the body may be well nourished, whereas, in other cases, these symptoms are associated with those denoting imperfection or disturbance of the digestive processes. A morbid sensitiveness of the digestive organs, and morbid sympathetic influences, appear to be the sources of the suffering in the cases referred to. On the other hand, when digestion is incomplete or disturbed, various symptoms arise in different cases, and with these there is sometimes comparatively little suffering. It is a curious apparent inconsistency that some persons manifest habitually more or less derangement of digestion, without much annoyance, while other persons habitually digest perfectly, but pass a wretched existence. The more prominent of the local symptoms in cases of dyspepsia may be arranged under the following heads: Regurgitations including pyrosis, cardialgia, tympanites, and vomiting.

Certain cases are characterized by regurgitations from the stomach. The liquid regurgitated is sometimes intensely sour from the presence of either the lactic, hydrochloric, or acetic acid. If the regurgitations occur, as is usual, during the progress of stomach-digestion, the acidity is probably due to chemical changes in the ingesta, but occurring, as is sometimes the case, after long fasting, when the stomach contains no food, it must come from the gastric glands. The regurgitated liquid is sometimes acrid, appearing to scald the throat; it may be greasy, or nauseous, having the odor and taste of rotten eggs, the latter denoting putrefactive changes. Some persons possess or acquire the faculty of voluntary regurgitation, and are able to expel, at will, the contents of the stomach—a faculty analogous to that of rumination in herbivorous animals.

The regurgitation of a considerable quantity of a liquid which is either insipid, or saltish or brackish, and sometimes acid, when the stomach is empty of food, and usually in the morning, is called pyrosis, or water-brash. Chambers supposes that the liquid is derived chiefly from the salivary glands, and that the collection is not within the stomach but at the lower part of the œsophagus.[1]

Cardialgia signifies pain at the cardiac orifice of the stomach, of a burning character, shooting into the chest, and up the œsophagus into the throat. It is vulgarly called heart-burn. Every one has occasionally experienced this symptom. It characterizes certain cases of dyspepsia, and is evidently dependent on the presence of an acid in the stomach, as it is quickly and completely relieved, for a time, by an alkaline remedy.

A painful sense of fulness after eating in dyspepsia is common, without any abnormal distension; but more or less distension from air or gas is a prominent symptom in certain cases, constituting tympanites. The tympanites may be situated in the stomach or small intestine. In most cases the gas is derived from putrefactive or fermentative changes in the ingesta. The nature of the gas will depend on the kind of food ingested. In the decompositon of albuminoid substances sulphuretted hydrogen is produced, and the gas expelled from the stomach has a characteristic fetor; the butyric fermentation furnishes hydrogen and carbonic acid gas, and the latter is also furnished by the acetic fermentation. The formation of lactic acid is unattended by the production of gas. The accumulation of gas within the stomach, if considerable, occasions painful distension, embarrasses respiration by interference with the descent of the diaphragm, disturbs the action of the heart, and interferes with the gastric peristaltic move-

[1] "The Indigestions," by Thomas King Chambers, M.D., etc.

ments. The formation of gas resulting from over-repletion of the stomach, may distend the stomach to such an extent as to cause sudden death. Two instances of this kind have fallen under my observation.[1]

Another source of flatulent distension is from gas secreted or evolved in some way independently of chemical changes in the ingesta. The accumulation is especially in the small intestine. Some persons suffer from an habitual tympanites. Females are more liable to it than males. Cases are occasionally met with in which the rapid development of tympanites occasions great suffering, the abdomen becoming enormously distended, the respiration embarrassed by interference with the descent of the diaphragm, and, in females, the suffering being increased by pressure upon the uterus and bladder. A case has recently been under my observation in which paroxysms of intestinal tympanites, occasioning intense distress, occurred daily for several successive months, an inodorous gas sometimes passing off by the rectum, and sometimes the tympanites disappearing without any escape of gas. A host of remedies were employed in this case unsuccessfully, and at length improvement has slowly taken place under simple palliative treatment. In a case of this description which I saw with my friend and colleague, Prof. Isaac E. Taylor, the appearance of the abdomen during an attack of tympanites was extraordinary. The convolutions of the small intestine and their peristaltic movements were distinctly visible through the distended abdominal walls. So far as my observation goes, such cases occur only among females, and the tympanites is associated with more or less neuropathic disorder. Hysterical phenomena are sometimes associated with it.

There is still another source of flatulent distension, the seat of the tympanites being the stomach, viz., the ingestion of air. More or less air is habitually commingled with food and drink, but the quantity received in this way is never sufficient to distend the stomach. A habit of swallowing air is sometimes acquired, resembling the trick which, in horses, is known as crib-biting or wind-sucking. Some writers refer to this habit as not uncommon, but the effort required in the deglutition of air is such that the act could not escape detection; and as I have met with only a single example, I must think that, in this country, cases are by no means frequent. The case just referred to I saw with my friend and colleague, Prof. Sayre. The patient was about fifty years of age, and had suffered from a disorder of the digestive organs for twenty-five years. In order to direct my attention to the difficulty, Prof. Sayre requested him to drink a tumbler of water. He drank it precipitately, and appeared to make violent efforts to force it downward. During these efforts the face became flushed and the eyes watery. Shortly the efforts were discontinued, and at the same moment a loud gurgling sound was heard in the region of the stomach. I supposed, at first, that there was obstruction at or near the cardiac orifice of the stomach, but, to show that the passage was free, Prof. Sayre passed readily a probang into the stomach. I was then at a loss what to think of the case, but Prof. Sayre had already arrived at the conclusion that the patient had the habit of swallowing air. The patient stated that the habit had existed for twenty-five years. He was led to it gradually in order to prevent regurgitation, which he stated always occurred if he failed to ingest air in conjunction with his food and drink. He was accustomed to belch air frequently. Percussion over the stomach showed considerable gastric tympanites. He declared that he could not

[1] Reported in Boston Med. and Surg. Journal, March 10, 1841.

overcome the habit, but promised to make the attempt. Nothing was heard of the case afterwards.

An habitual tympanites of the stomach occasions, in some persons, after the ingestion of liquid, a succussion sound in walking, resembling the sound frequently heard in horses. This is a source of much annoyance and mortification, especially in females. It may be avoided by taking into the stomach only very small quantities of liquid at a time.

Vomiting is not common in cases of habitual dyspepsia. It is more frequent in occasional fits of indigestion or in acute dyspepsia. It is, however, characteristic of a form of chronic dyspepsia occasionally met with, occurring generally in young females. In this variety of disorder, vomiting almost constantly follows the ingestion of food or drink; the stomach seems to be intolerant of all forms of nourishment, although taken in small quantities. The vomiting occurs directly or soon after food is taken, and, in some cases, it is surprising that there is not more evidence of inanition, since everything taken into the stomach appears to be ejected; yet, although the disorder may continue for a long time, the patient does not become greatly emaciated nor notably enfeebled. The disorder is apt to resist all the usual remedies to relieve irritability of the stomach, such as bismuth, creasote, opiates, hydrocyanic acid, oxalate of cerium, etc. It is usually accompanied with mental depression, hyperæsthesia of the surface, and marked tenderness over the spinal column. In determining that the affection is purely functional, gastritis, gastric ulcer, subacute meningitis (especially in children), pregnancy, and disease of the kidneys are to be excluded. The treatment adopted in a case of this description by William Hunter (which has been often quoted) will sometimes prove effectual, viz., restricting the patient to a very small quantity of some bland nourishment, such as milk or animal essence, taken at short intervals. But the plan of treatment which, in my experience, has proved most successful, consists in change of scene, and living as much as possible out of doors. I have known a sea-voyage to prove efficacious.

The local symptoms just noticed are not peculiar to dyspepsia. They may occur in connection with subacute gastritis and structural lesions of the stomach. In arriving at the diagnosis of dyspepsia—that is, determining that a functional affection only exists—inflammation and the lesions which have been considered are to be excluded. They are to be excluded by the absence of their diagnostic symptoms, and for these the reader is referred to the preceding chapters.[1]

Of symptoms other than those referable directly to the stomach and small intestine, mental disorder is one of the most noticeable. During the processes of digestion, dyspeptics are apt to experience an uncomfortable heaviness or dulness, rendering it difficult to concentrate the attention upon any subject. The following extract from Chambers's work gives a truthful representation of the condition in many cases: "There is great languor and incapacity for exertion, coming on generally about an hour after food, and accompanied in some cases by an almost irresistible drowsiness, which lasts for several hours. This symptom is particularly marked in the afternoon, if the patients dine in the middle of the day and endeavor to continue their employment afterward. Yielding to the drowsiness and taking a siesta seem to make matters worse, for there is usually felt after such an indulgence an intense headache or giddiness, which continues longer than the

[1] Diarrhœa dependent on intestinal indigestion will be considered in the next chapter.

symptoms would have done had the inclination to sleep been resisted. The depression of spirits is not so remarkable as the feeling of utter helplessness, both of mind and body, accompanied in persons naturally active with a sense of shame at their unwonted apathy."[1] This condition may be connected with the process of digestion in the small intestine, and may be unaccompanied by symptoms denoting disorder of stomach-digestion.

In most cases of dyspepsia, patients suffer more or less from mental depression. They are devoid of buoyancy, gloomy, and disposed to look always on the dark side. Frequently this depression is increased by anxiety respecting health. They are apprehensive of the existence of some grave disease, such as consumption or an affection of the heart. Impotency is sometimes fancied. Their attention becomes concentrated upon themselves. They are constantly watching the sensations connected with digestion, and fall into the habit of counting the pulse, feeling the heart's beat, examining the abdomen, urine, etc. This mental disorder, carried beyond a certain point, eventuates in the forms of mental aberration known as melancholia and hypochondriasis.

In addition to these symptoms of mental disorder, various symptomatic phenomena belong to the clinical history of dyspepsia. Irregular action of the heart, or palpitation, is not uncommon. Constipation generally exists, sometimes alternating with diarrhœa. The skin is apt to be dry and rough; the extremities are often cold, showing deficient activity of the circulation; the tongue is usually furred or more or less coated. The urine deposits the lateritious sediment, and, on microscopic examination, crystals of oxalate of lime may be found in abundance—the latter, being incidental to various morbid conditions, and not uncommon in connection with trivial disorders, are incorrectly considered as denoting a special affection called *oxaluria*. Vigilance is a frequent source of complaint, and the sleep obtained is often incomplete and disturbed by dreams, the patient arising in the morning unrefreshed and miserable.[2] The appetite in the morning is often poor, becoming, perhaps, during the day, morbidly craving. A dry hacking cough is reckoned among the sympathetic phenomena, but, in my experience, this is rare. The existence of cough should always excite suspicion of pulmonary disease or of chronic pharyngitis; the latter is quite common.

With reference to the pathology of dyspepsia, it is to be considered that digestion is not a simple process. Including under this term all the changes which take place in the ingesta prior to absorption, there are certain changes in the stomach from admixture with the salivary fluids and the gastric juice, others in the duodenum from the addition of the bile and pancreatic secretion, and others in the small intestine, below the duodenum, from the action of the intestinal juice. For the proper activity of the organs, and for the secreted liquids, the latter being vastly more abundant than was formerly supposed, a large supply of blood is required. The movements due to the muscular coat of the stomach and intestine are important. A certain influence derived from the nervous system, called innervation, is requisite for the secretion of the liquids and the peristaltic movements. An analysis of the symptomatic phenomena in different cases of dyspepsia shows that the different elements which enter into the function of degestion may be affected either separately or with different degrees of predominance.

[1] Digestion and its Derangements. American edition, page 367.

[2] The poet Cowper, who appears to have suffered from intense mental depression in connection with dyspepsia, describes his feeling in the morning in the following forcible language: "I awake like a toad out of Acheron, covered with the ooze and slime of melancholy."

Thus, vomiting and regurgitation show irritation and spasmodic action; pain or distress, morbid sensibility; prolonged digestion with chemical changes, deficiency in the digestive liquids, etc. It is of importance to take cognizance of these several elements in the management. The period which elapses after eating before the inconvenience is felt, and the absence of symptoms of disorder referable to the stomach, go to show intestinal rather than gastric dyspepsia.

The causation of dyspepsia involves agencies affecting the digestive processes either directly or indirectly. Excesses in eating and drinking act as direct causes. The digestive powers may be overtasked by the quantity, or over-excited by the quality, of food. Under these circumstances, dyspepsia has been humorously called "the remorse of a guilty stomach." The habit of spirit-drinking engenders dyspepsia; drunkards after a time become dyspeptics. Dyspepsia may follow subacute gastritis or enteritis produced by dietetic errors or other causes; inflammation leaves the organs in a weakened state. These direct causes, however, are not so largely operative as is generally supposed.

The indirect, more than the direct, agencies are involved in the causation. These are various. Anæmia is one of the direct causes. It gives rise to dyspepsia by diminishing the functional activity of the gastric and intestinal glands, the digestive liquids being lessened, or affected in regard of their quality. Clinical observation shows that, in cases of anæmia, the digestive processes are generally more or less disordered. On the other hand, disordered digestion may stand in a causative relation to anæmia. A notable change in habits as regards physical exercise not infrequently gives rise to dyspepsia. The vigor of the digestive organs is in a measure commensurate with the demand for nutritive material, and the latter is dependent on the waste of the tissues. Now, certain dietetic habits are formed in accordance with occupations involving physical activity and a proportionate amount of disassimilation. Persistence in these dietetic habits after a change from an active to a sedentary life is apt to induce disorder. This is, in part at least, an explanation of the occurrence of dyspepsia among those who exchange the farm or workshop for the desk or study, and among those who retire from business to become men of leisure.

In a large proportion of cases, dyspepsia originates and is perpetuated by mental causes. It is induced and kept up by anxiety and depression. Disorder is often, in the first place, produced by mental causes, and then the dyspepsia reacts upon the mind, increasing its morbid condition. An examination into the previous history of cases of dyspepsia will frequently show the affection to have been preceded by mental inquietude of some sort. Persons of a certain mental constitution are especially prone to dyspepsia, viz., those so constituted as to be constantly anxious about something, such as acquiring success in life, getting out of debt, securing an independent position, or about imaginary troubles. The period of life when persons are most prone to dyspepsia is that in which anxieties are apt to be greatest, viz., between adult age and middle life. After the latter period, the events of life are taken more calmly, and there are fewer sources of intense anxiety. Persons who have been dyspeptics for many years are often free from this affection after having entered upon middle life. It may be doubted if the affection is often produced by overtasking of the intellect. When it occurs in those who are excessively devoted to intellectual pursuits, it arises generally from the sedentary habits connected with these pursuits or from mental anxiety; on the other hand, deficient exercise of the intellectual and moral faculties is apt to lead to it. Conditions in life involving ennui and dissatisfaction predispose to it. Under

these circumstances the attention is apt to become concentrated on the functions of the body, which go on best without close surveillance. These views are sustained by observing the classes of persons who suffer from dyspepsia. Epicures and gormandizers by no means of necessity become dyspeptics; they often escape this affection when their indulgences lead to other consequences, such as gout, etc. The laboring classes are not prone to dyspepsia, notwithstanding the use, frequently, of the coarsest and most indigestible kinds of food, prepared without any regard to the art of cookery. But cases of dyspepsia are met with especially among retired rich persons, without occupation or mental resources, among those who have no useful or proper aims in life, and among those who are debarred from the interests of domestic life; and in these classes it may be developed irrespective of any dietetic errors.[1]

Treatment.—In the management of dyspepsia, as of other affections, the first point is to remove or obviate causes, in so far as this is practicable. The practitioner may be able to control causes relating to dietetic errors, but he may not be able to reach those connected with the mind, and hence a difficulty in effecting a cure. Measures of treatment may be arranged in three divisions, viz., 1st, those relating to diet and regimen; 2d, measures addressed to the mind; and, 3d, medicinal remedies.

1. If the affection have been induced by dietetic excesses, it is sometimes useful to give the digestive organs a short period of rest, and, with this view, to reduce the diet, for a time, below the wants of the system. This, however, should be but temporary. A cure is not to be effected by persisting in this course. Not only the system is reduced, but the digestive functions are impaired by too great or too protracted abstemiousness. Dyspepsia is, in fact, perpetuated, if, indeed, it be not sometimes produced, by attempts to live on as little and as coarse food as possible. Persons who think it vulgar, unrefined, or worldly-minded to eat well are apt to be the subjects of dyspepsia, as well as of other affections. The object of treatment is to bring the digestive powers up to such a point of improvement that particular care in diet is not requisite.

As regards the diet for dyspeptics, there are no rules suited to all cases. Individual experience, in each case, is to be a guide, but there is a liability to error in regard of this experience. Unusual difficulty or disturbance of digestion after a meal is often imputed by the patient to certain articles of food, when it was due to some other incidental circumstance. Idiosyncrasies in relation to particular articles of food are far less common than the statements of patients would lead one to suppose. In general, articles which are wholesome to most persons are not unwholesome to any. It is rarely true that "what is one man's meat is another's poison." As a rule, when a patient says that he cannot take such and such articles which general experience shows to be digestible and nutritious, it is fair to presume that he is deceived, and of this the patient may generally be convinced if he be persuaded to persist in their use. At first, the expectation that an article will prove hurtful contributes to render it so; but, after a time, the idea is overcome. It is often an object in the treatment of dyspepsia to do away with these fallacious ideas respecting various kinds of food. Some persons seem to be fond of encouraging the notion that their digestive organs are endowed with peculiar susceptibilities which prevent them from conforming to general rules of diet. In most cases of dyspepsia,

[1] For a fuller exposition of these views of the causation of dyspepsia, *vide* article by the author in the American Journal of Med. Sciences, January, 1841.

animal food is best digested, especially old and tender meats plainly but well cooked; but, in some cases, a milk and farinaceous diet is found to agree best. An obvious reason why so many persons imagine they do not digest milk well is, it is generally taken as a beverage after or with solid food, the fact that it is, in effect, a solid article of food not being appreciated. Bread, to be readily digestible, should not be new, nor is it desirable that it should be stale. Well-boiled rice and corn-meal mush are easy of digestion. Crude vegetables are apt to be digested with difficulty in cases of dyspepsia, but not invariably. Some dyspeptics find even the much abused cucumber grateful to the stomach as well as to the palate. Pastries, rich puddings, and sweetmeats are generally to be eaten sparingly or discarded. Ripe fruits in moderation are useful. It is generally not advisable for the patient to limit himself to a restricted range, or to adopt any particular system of diet. On the contrary, he should persevere in attempting to digest all the varied forms of wholesome food, not confining himself to meat or a vegetable diet, but aiming to eat like persons in health, without the need of particular care in the selection of food.

Different kinds of food are suited to different cases according as the functional disorder is chiefly gastric or intestinal. If gastric, farinaceous articles will be likely to be best suited, as these are digested mainly in the small intestine. Fatty articles may be well digested in these cases. On the other hand, if the disorder be intestinal, farinaceous and fatty articles of food will be likely to be difficult of digestion, and albuminoid substances or an animal diet will be best borne.

Regularity in meals is a point of importance. Frequently more than three meals a day are advisable. If a patient have no appetite for breakfast, an early lunch should be taken. If he dine near the middle of the day, and have an early tea, some light food in the evening is advisable. Long intervals between the periods of taking food tend to weaken the powers of digestion. The quantity of food taken at a meal is to be graduated to the diminished digestive powers. The appetite is not always to be relied upon in dyspepsia. The appetite is often craving; the system calls for nutritive supplies beyond the ability of the digestive organs to prepare food for assimilation. Food should be eaten slowly. Deliberate mastication prepares the food for the action of the gastric juice. Moreover, slowness in eating gives the stomach a chance to express satiety, and is, therefore, a protection against over-eating. A moderate quantity of liquid only should be taken at meals, in order not to dilute too much the gastric juice, but drink may be taken freely between the acts of digestion. Under erroneous notions, abstinence from liquid is sometimes carried to an extreme.

With regard to the use of wine or spirits, the danger of intemperance is always to be considered, especially as dyspepsia not infrequently leads to a morbid desire for stimulants, and in view of the fact that the mental state is favorable for the formation of intemperate habits. Yet an alcoholic stimulant taken with meals is often useful until the normal powers of the digestive organs are restored. If spirits be taken, they should be as little diluted as possible, the object being to stimulate the stomach. Stimulants should never be taken when the stomach is empty.

Tea and coffee are sometimes hurtful, the latter especially. Tobacco is often injurious, from the waste of saliva and the depressing effect on the nervous system. If used at all, the quantity used should be quite small, and, in general, total abstinence is easier than moderate indulgence.

Finally, with regard to diet, it may be well to remind the practitioner that it is unphilosophical to judge concerning his patients from his own

personal experience. The physician who has his notions of what kinds of food agree with himself best, is apt to apply these notions indiscriminately to his patients.[1]

As regards regimen, the clothing of dyspeptics should be such as will secure uniformity of temperature and maintain the functions of the skin, without an over-accumulation of heat or exciting perspiration. Exercise is of great importance; but to be as useful as possible, it must be taken with a motive and end, aside from the sanitary object. Exercise, taken simply as exercise, tends to keep the mind of the patient on his disorder, and will not be likely to be persisted in. There is a risk of resorting at once to over-exercise, a too violent change of habits in this regard proving hurtful and discouraging the patient. The exercise should be in the open air. A change of business from one requiring sedentary habits to one involving out-of-door occupation is often advisable. Travelling, especially in foreign countries, where the attention is diverted with a succession of novel scenes, is highly useful. Sir James Johnston said that no case of purely functional dyspepsia could resist a pedestrian tour over the Alps.

2. The moral treatment consists first in establishing confidence by attention and sympathy. Inattention to the details into which dyspeptic patients are fond of entering, and ridicule of hypochondriacal fears prevent the physician from being of service to this unhappy class of patients, and lead them to seek for aid from quack remedies and quacks. If the confidence of the patient be secured, the assurances of the physician will often remove needless apprehensions, and afford an encouragement which, in itself, will contribute not a little toward improvement. If the patient be convinced that his mental state is in a measure due to a disordered condition of the body, he derives consolation and encouragement from this belief. The treatment relating to the mind will embrace, as far as possible, measures having reference to the removal of mental causes which may have produced or which perpetuate the affection. It is important to incite to occupations which divert the attention from the bodily functions, especially during the process of digestion. It is desirable that the mind should be pleasantly occupied. It is often observed by dyspeptics that if they dine alone, and are left by themselves to watch the sensations connected with digestion, they are sure to suffer, whereas they experience no inconvenience from a greater amount of indulgence in eating if they be in agreeable company during and after dinner. Popular works on indigestion do harm by directing to the subject the attention of those prone to dyspepsia. The benefit of travel is, in a great measure, moral, involving recreation as well as exercise, and keeping the mind occupied with extrinsic objects.

3. The division of the treatment which relates to medicinal remedies is, relatively, least important, but by no means unimportant. If the symptoms denote morbid sensibility of the stomach, counter-irritation on the epigastrium is often useful. Small blisters, the strong aqua ammoniæ, or the croton oil, may be used for this purpose. The benefit is, probably, in part, due to a moral effect. The nitrate of silver may be tried in these cases, care being taken not to continue it too long. If anæmia be associated, the chalybeate tonics are indicated, of which, in cases of dyspepsia, the tincture of the chloride of iron is one of the best. The citrate of iron and quinia is an excellent form of tonic in dyspepsia associated with anæmia. The powder of iron reduced by hydrogen is another eligible form.

[1] It is perhaps hardly necessary to state that these few remarks on diet in cases of dyspepsia are designed only as hints for the practitioner. To consider the subject of dietetics fully would be incompatible with the scope of this work.

If there be constipation, the bowels are to be regulated by appropriate measures, but purgation is to be avoided. Constipation will be considered as a distinct functional affection. There are no special indications for mercurial remedies except as an occasional cathartic or laxative. The success of the Abernethean plan of giving frequently blue mass followed by the infusion of senna, was doubtless due to a moral effect, in conjunction with advice as regards diet and regimen. In general, the various vegetable tonics are useful, the form of tonic being varied from time to time. A grain or two of quinia twice or thrice daily, continued steadily for several weeks, appears to be often useful. A few drops of hydrochloric acid just before or after eating, may frequently be prescribed with advantage. The benefit of the tincture of the chloride of iron is, probably, in part, due to the hydrochloric acid. Of late, pepsin has been somewhat in vogue as a remedy in dyspepsia. Experience does not appear to offer much testimony to its value. The principle on which it is employed, viz., to supply a deficient element in the gastric juice, entitles it to be considered only a palliative, not a curative, remedy. A convenient and eligible form in which pepsin may be given is the preparation commonly known as rennet-wine. This is prepared by putting a fresh rennet, cut up into small pieces, into a pint of sherry wine, which, after maceration for two weeks, is to be strained, and it is then ready for use. Of this preparation, from half a teaspoonful to a teaspoonful is to be given at the time of, or shortly after, taking food. This remedy is useful, not only in cases of dyspepsia, but in various diseases when it is desirable temporarily to resort to artificial digestion.

Symptoms characterizing certain cases of dyspepsia claim particular remedies. Pyrosis is generally relieved by bismuth in full doses, in conjunction with measures relating to diet, regimen, etc., and followed by tonic remedies. The purified oxide of manganese is stated by Dr. Leared, of Dublin, to be equally, if not more, efficacious in relieving this form of disorder. The dose is from ten to thirty grains, given three times daily. Cardialgia calls for alkaline remedies, viz., lime-water, liquor potassæ, subcarb. of soda, magnesia, the two latter especially if there be constipation. Flatulency and tympanites are to be relieved by carminative stimulants, the tincture of the essential oils, the aromatic powder, and charcoal powder, the latter being useful on account of its faculty of absorbing gases. All these remedies, however, are merely palliatives. The conditions on which depend the several symptoms just named, are, if possible, to be removed by tonic remedies, such as quinia, and the mineral acids. Tympanites occurring in paroxysms, from the secretion of gas, is apt to be an extremely obstinate form of disorder. Purgatives are not useful. Opiates to relieve present suffering are required. Carminative and alcoholic stimulants will sometimes afford relief. Assafœtida given by the mouth or rectum is highly useful, especially when hysterical symptoms are associated. In the intervals between the paroxysms, measures, medicinal and hygienic, to invigorate the system are indicated, together with the use of antispasmodic remedies, such as belladonna, valerianate of zinc, etc. My friend, Prof. Isaac E. Taylor, has found small doses of strychnia useful in these cases. This remedy, or the nux vomica in the form of tincture or extract, is highly recommended by many in other forms of dyspepsia. The doses should be sufficiently small to avoid any possibility of inducing poisonous effects.

The management in certain cases of dyspepsia characterized by persisting vomiting after taking food, has been already alluded to. Change of scene and out-of-door life are the most efficient measures. A sea-voyage

will be likely to prove effectual. But various remedies may be employed in succession, each of which will sometimes be found useful, if not successful. The salts of morphia or codeia may succeed if the patient be not unpleasantly affected by opiates of any kind. If immediately rejected from the stomach, these remedies may be given by means of hypodermic injections. The hydrocyanic acid, in some cases, is an efficient remedy. Creasote sometimes acts efficiently, given in doses of one or two minims, repeated after each act of vomiting. In young children this remedy, given in doses of one-eighth or one-sixth of a drop, frequently acts like a charm in arresting vomiting. Bismuth in large doses is a valuable remedy in some cases. Strychnia or the nux vomica has been found useful. The oxalate of cerium, from one to two grains at a dose, is another useful remedy. Counter-irritation on the epigastrium; by means of blisters or dry cupping, is frequently followed by relief. Milk with lime-water added is sometimes retained when other articles of food are rejected.

Vomiting is symptomatic of a great variety of affections, exclusive of inflammation or structural lesions of the stomach. Occurring as a form of functional disorder of the stomach, it is sometimes considered as an individual affection; but it may with propriety be included under the head of dyspepsia. There is a variety of vomiting which claims a brief separate notice. Reference is had to cases in which a liquid is thrown from the stomach in greater or less abundance, emitting an odor of fermenting wort, and, after standing a few hours, becoming covered with a mass of brownish froth resembling yeast. Goodsir, in 1842, on subjecting this liquid to microscopical examination, discovered in great abundance a vegetable fungus, which is now commonly known as the *sarcina ventriculi*, called by Robin *merismopœdia ventriculi*. The sarcinæ are distinguished by their oblong or square form, and by their being divided by lines into four equal squares, so that they resemble a package tied with a cord, as the name sarcina denotes. The vomited liquid containing sarcinæ may also contain the yeast fungus in abundance. The liquid is sour, due, according to Budd, to acetic acid, and the vegetable productions are incidental to a process of fermentation, attended with the formation of this acid, together with the evolution of carbonic acid.

There does not appear to be ground for the belief that the presence of the vegetable productions is the source of disorder. They are effects, rather than the cause, of disorder. The sarcinæ are not produced exclusively within the stomach; they have been found in the urine, in the purulent discharges from a gangrenous abscess, and in the humors of the eye. Their production within the stomach appears to be owing to an undue retention of its contents, from pyloric obstruction or other causes. The treatment, therefore, relates, not alone to the circumstances immediately involved in their production, but to the morbid conditions giving rise to these circumstances. Remedies, however, designed to arrest the fermentative process are indicated. And, of these, the most efficient is the bisulphite of soda, first suggested as a remedy in this form of disorder by Jenner. From fifteen grains to a drachm may be given, dissolved in water, two or three times a day. Budd's method of employing this remedy is to prescribe a solution of the strength of two drachms of the salt in an ounce of water, and to direct a teaspoonful to be taken in a wineglass of water soon after meals, or when the fermentative process in the stomach is about to commence. According to the author just named, the remedy owes its efficacy to the fact that it is easily decomposed, and its decomposition liberates sulphurous acid, which prevents alcoholic and acetous fermentation. The sulphite of soda, and the other sulphites, are valuable as palliatives when-

ever, from defective power of digestion, fermentative processes in the ingesta take place. The value of these remedies, in cases of dyspepsia, depends on their power in arresting fermentation.

Dyspeptics frequently derive advantage from the use of mineral spring waters, especially if connected with a sojourn, under agreeable circumstances, at a pleasant watering-place. Much of the advantage, doubtless, is due to the change of habits, relief from care, together with the moral influence of the expectation of improvement. Of the various mineral waters, those from the gaseous and chalybeate springs are best suited to cases of dyspepsia. Cold sea-bathing, and the invigorating influence of a bracing sea-air, are frequently useful. The hygienic discipline of the hydropathic system is undoubtedly useful in some cases, the benefit being due, probably, in part, to a physical, but more to a moral effect. There is, perhaps, no affection in which the anticipation of improvement from the employment of certain measures contributes to their efficacy more than in dyspepsia.

POLYPHAGIA, MALACIA OR PICA, POLYDIPSIA, AND DIPSOMANIA.

These names express morbid conditions which relate to the ingestion of solids or liquids; conditions which, severally, do not constitute individual affections, but which may be the most prominent, or perhaps the chief, ailments, and, therefore, they claim a passing notice.

Polyphagia, or, as it is more commonly called, *bulimia*, denotes a craving for food beyond the wants of the system. As thus defined, these terms are not correctly applied to the greatly augmented appetite felt frequently during convalescence from fevers and other acute diseases, or when, from any cause, the system for a time has been deprived of alimentary supplies adequate to its wants. The inordinate desire for food, under these circumstances, is an expression of the requirements of the system, and the ability to digest food may be proportionately augmented—a fact which illustrates, in a striking manner, the connection existing between nutrition and the function of digestion. True bulimia does not exemplify this physiological connection; the amount of food craved far exceeds the requirements for nutrition. Bulimia may be another name for gluttony. The love of eating may be cultivated to such an extent that little else is thought of, and persons who fall into this habit may be said to live to eat, rather than eat to live. The observation of every one will furnish examples of this kind. Habits of gluttony may lead to dyspepsia, which, by interrupting further indulgence, proves conservative, or, if the digestive function continue active, they may lead to obesity, fatty degeneration of the heart or other organs, and to various affections. Voracious eating characterizes certain cases of mental derangement. It may be a symptom of disease attended with progressive waste, for example diabetes. In a more marked and rare form, the craving for food greatly exceeds that under the circumstances just named. Curious instances have been reported, in which the morbid appetite appeared to be insatiable, all kinds of food, raw meat, candles, etc., being eaten, in some cases, with avidity, and in enormous quantity. It is difficult to explain the morbid appetite in these instances. Recovery from this condition may be expected. The indications are to regulate the diet as far as possible, to establish the general health by hygienic measures, to correct any disorder of digestion which may exist, and to palliate the excessive craving for food by opium or, sometimes, by

nauseant remedies. Swallowing pieces of ice has been found effective as a palliative measure.

Malacia and *pica* are terms applied to perversions of appetite, that is, to a morbid craving for particular substances. The terms are commonly used as synonyms, but, strictly, they denote different kinds of perversion. Malacia denotes a morbid craving for certain articles of food or articles which are not devoid of nutrition, whereas, pica denotes a desire for innutritious substances. The craving for strange kinds of food, sometimes attending pregnancy, and commonly known as *longings*, is sufficiently familiar. Similar eccentricities of the appetite are sometimes observed in connection with hysteria, and they may be due, in some cases, to that desire to become objects of wonder or interest which weak-minded hysterical women sometimes evince. Unnatural and disgusting perversions of the appetite are among the symptoms occasionally met with in cases of insanity. Perversions falling under the head of pica are sufficiently common. Innutritious substances frequently craved are charcoal, chalk, slate, and certain kinds of earth. The habit of eating these substances is sometimes carried to a great extent. In the case of a young lady seized, shortly after marriage, with epidemic dysentery which proved fatal, the dejections contained an enormous amount of a black substance which, on investigation, was found to be from a species of slate-stone which she was accustomed to eat daily in excessive quantity. In some cases of pica, the articles are at first taken with the idea of improving the complexion, and in this way the habit is formed. But, in other cases, a morbid uneasiness in the stomach leads to their use. The appetite is mostly confined to females, and is generally associated with spontaneous anæmia or chlorosis. The measures of treatment are to be addressed to the associated disorders, the continued indulgence of the perverted appetite being interdicted.

Dirt-eating, as vulgarly called, or *chthonophagia*, is a morbid habit which has heretofore prevailed, to a considerable extent, among the plantation negroes of the Southern States. It was described by John Hunter as prevailing among the negroes of the West Indies. The kind of earth selected is a loam or clay. Dr. James B. Duncan, of Louisiana, in a paper contained in *Fenner's Southern Reports*, vol. i. 1850, gives the following account of this form of pica: "A very common disease among negroes on plantations in this part of the county, is a *state of anæmia* very often attributed, and perhaps justly, to the pernicious habit of *dirt-eating*. On examining negroes on a plantation, a medical man is surprised to meet with so many of these cases. Almost every large plantation has three or four, and sometimes more of them. Until the vital powers of the system are beginning to be undermined, no marked symptons of disease being visible to the eye of the planter, they are generally suspected of laziness or malingering. After this condition has existed for some time, the skin presents a paler hue than natural; or if the subject is a mulatto, an ashy white; the lips, tongue, lining membrane of the mouth, the palms of the hands, white, lacking the reddish tinge of health; the legs œdematous, abdomen distended, pulse full, soft, and frequent; action of the heart violent; if blood is drawn, it is pale and watery; respiration on the slightest exertion hurried; in fine, all the symptoms which characterize *chlorosis* in females. We find this condition of things in subjects of both sexes. Many of these cases are, doubtless, produced and aggravated by the deleterious habit of dirt-eating. But I never heard a negro admit that he was addicted to the habit. Some admit that formerly, years ago, they ate dirt, but not now; and others, trusty, truth-telling negroes on

other subjects, on this will lie most pertinaciously to the last, unless detected in the act. With many, no doubt, dirt-eating is a symptom only of a diseased condition of the digestive organs, and of the system generally. With them dirt-eating proceeds from the same propensity which leads white females to resort to chalk, magnesia, etc., in order to relieve a disordered acid condition of the stomach. This condition of system is often, in my opinion, produced by a deficiency of suitable nutriment. The diet of negroes on most plantations being salt pork, corn bread, and molasses—rarely fresh meat and vegetables—a condition of the system is thus produced closely allied to scurvy. In addition to the symptoms above described, I have occasionally seen a spongy state of the gums.

"The restoration of these cases to health, whether addicted to dirt-eating or not, is troublesome and tedious. The *moral* has to be prescribed for, as well as the *physical*, symptoms. To restore the healthy condition of the body, nutritious food, fresh meats, vegetables and greens, porter or wine, are necessary; and, as to medicinal agents, preparations of iron in any or all forms, combined with stimulating stomachics and bitter tonics, laxatives when indicated, and out-door exercise. Confinement within-doors aggravates the disease. To cure the habit of dirt-eating, many resort to cruel methods of preventing the indulgence of it, by tin masks for the face, iron gags, chaining on plank floors, etc. By using these means, it is true, the habit cannot be indulged in, but the cause that produced the propensity still exists, and the disease cannot be cured so long as these depressing agents are used. Restore the healthy tone of the system, invigorate the subject, put rich blood into his veins, clothe him well, feed him well, and do not overtask him; arouse his feelings of pride, teach him to feel that he is a reasonable and rational being, and, in a majority of cases, success will attend our efforts, and we shall have the satisfaction of rescuing a valuable servant from the grave."

Polydipsia is a term applied to denote a condition characterized by an excessive craving for liquids. Water is drunk in a very large or enormous quantity, amounting sometimes to several gallons in the twenty-four hours. In some cases the patient experiences constant or frequently recurring thirst, associated with dryness of the tongue and fauces. He is unable to sleep except for short periods, in consequence of the urgency of the desire for drink. The quantity of urine is proportionately great, so that this condition is also denoted by a term expressing the latter fact, viz., *diabetes insipidus*. The urine voided has but little specific gravity, presenting a clear limpid appearance like pure water, and containing neither sugar nor any abnormal constituent. In other respects, the health may not be notably disordered. The appetite and digestion may be unimpaired, the functions generally are well performed, and the body does not waste. This condition at first suggests to the physician the probable existence of diabetes mellitus, but an examination of the urine leads to the exclusion of the latter disease. The condition may occur in early life or becomes developed at any age. It has been observed to occur as an intermittent malady, but, in general, it continues for an indefinite period or during life. It does not appear to lead to any disease, and is serious, in itself, only on account of the annoyance and debility which it occasions. Its pathological character, with our present knowledge, cannot be satisfactorily explained. Existing to the extent just described, it is so rare as to belong among the curiosities of clinical experience. In our ignorance of the pathology, there are no rational indications for treatment, and experience has not furnished any reliable means of cure. Opium, valerian, camphor, and other antispasmodics have been found to diminish

the thirst temporarily, and some benefit has been derived from the use of various tonic remedies.

Dipsomania is a term sometimes used to denote the peculiar delirium arising from the abuse of alcohol, but it is commonly applied to an insatiable desire for alcoholic drinks, and, used in this sense, it expresses a morbid condition which may be noticed in the present connection. A craving for this class of stimulants is sometimes developed in cases of dyspepsia, and may be the source of intemperate habits. This fact has been already referred to. It is not to be lost sight of in judging of the propriety of prescribing or sanctioning the use of alcoholic stimulants in dyspeptic cases. A morbid craving for alcohol in some form is an element of intemperate habits, whatever may have been their source. The habitual drunkard feels a desire for continued indulgence, which, with an impaired power of self-control and lessened self-respect, resulting from intemperance, he is, after a time, wholly unable to resist. It is useless, under these circumstances, to attempt to reason him into temperance; he may appreciate the force of all the arguments which are presented, but he lacks moral strength enough to govern an acquired appetite which represents a morbid condition as much as the delusions of insanity. Reason and persuasion, however, may be effective before this condition of dipsomania is reached; that is, they may prevent this condition by leading to abstinence from alcoholic stimulants. Dipsomania is to be treated as a disease of body and mind. The cure is to be effected by withdrawing the patient from the use of alcohol in any form, and the employment of medicinal and hygienic measures to invigorate the physical and mental faculties. The treatment must be continued long enough for the cessation of the morbid craving for stimulants, and for the development of moral strength sufficient to enable the patient to adhere to a course of total abstinence, in which consists his only safety. It is evident that successful management is rarely practicable, except by means of institutions in which the patient is under the same restrictions as in insane asylums. In fact, dipsomania is to be treated as a form of mental derangement.

There is a species of dipsomania which is constitutional and congenital. The desire for stimulants is paroxysmal, and an irresistible craving is developed by ever so small an indulgence. Persons with this unfortunate idiosyncrasy lose their power of self-control as soon as they feel the influence of alcohol. The only protection against inebriation, in such cases, is rigid abstinence.

Connected with the subject of dipsomania are questions pertaining to the causes of intemperance, and the means of its prevention, which are of the utmost importance to the welfare of mankind, but which do not properly fall within the scope of this work. The morbid effects of alcohol upon the system, aside from the development of dipsomania, will be referred to in connection with different individual diseases, and especially those affecting the nervous system.

GASTRORRHAGIA.

Hemorrhage into the stomach, and vomiting of blood, are denoted by the term *Hæmatemesis*. The term *Gastrorrhagia* is in uniformity with the rule of nomenclature by which a hemorrhage and its situation are expressed, and is, therefore, to be preferred. Moreover, the term gastrorrhagia applies to all cases of gastric hemorrhage, whether vomiting take place or not, the blood sometimes not being expelled by the mouth, but passing into the intestinal canal and being evacuated from the bowels.

In the great majority of the cases in which hemorrhage takes place into the stomach, blood is vomited; and, more or less blood also passing into the intestinal canal, the stools present appearances to be described under the head of enterorrhagia.

When blood is expelled from the mouth, the first point is to ascertain the source of the hemorrhage. It may be from the mouth or posterior nares. Coming directly from either of these sources, it is traced without difficulty; but if blood be swallowed and vomiting occur, it may sometimes be a question whether gastric hemorrhage exists or not. In cases of bronchorrhagia, blood may be swallowed and vomited. In a child too young to expectorate, bronchial hemorrhage might thus be supposed to be gastric. Examples have occurred, but both bronchorrhagia and gastrorrhagia in young children are extremely rare. The rupture of an aneurism into the pharynx or œsophagus is another source of hemorrhage which may appear to be gastric. But, in general, the question is, whether the blood come directly from the stomach or air-passages. The points involved in this differential diagnosis have been already presented in treating of bronchorrhagia, and need not be here repeated.[1] Blood which has been vomited, in most cases presents a dark grumous appearance. Exceptionally, it is florid, like arterial blood. It then comes from an artery, and has been vomited directly it accumulates within the stomach.

Gastric hemorrhage, in the vast majority of cases, has no claim to be regarded as an individual affection. It may be a symptom of carcinoma of the stomach, or of gastric ulcer, and, as such, has been already considered. It is an occasional effect of portal congestion in cases of cirrhosis of the liver. It coexists with hemorrhage in other situations in cases of purpura hemorrhagica and scorbutus. It occurs in cases of acute gastritis. It is a prominent event in the natural history of yellow fever; the so-called black vomit, in this disease, denoting neither more nor less than gastrorrhagia. Exclusive of these pathological associations, it may occur in place of the menses in cases of amenorrhœa. Instances in which gastrorrhagia is to be regarded as vicarious menstruation are by no means common. In the majority of the cases in which it follows suppression of the menses, it proceeds from disease of the stomach. Yet, that it may take the place of the menses, must be admitted. Of 27 cases of gastrorrhagia analyzed by Valleix, in 5 the hemorrhage could not otherwise be accounted for; and in all these cases recovery took place. The cessation of habitual hemorrhage in some other situation, the arrest of purulent discharges of long standing, and the healing of old ulcers, have been supposed to stand, occasionally, in a causative relation to gastrorrhagia, but this supposition does not rest on adequate clinical proof. Hemorrhage sometimes occurs from the stomach, as from the bronchial tubes, the Schneiderian membrane, and in other situations, without any apparent pathological connections, neither following nor preceding any appreciable morbid conditions. It is then to be considered as idiopathic, or as constituting an individual affection. Such cases are much more infrequent than cases of idiopathic bronchorrhagia. Hemorrhage from the stomach is an occasional event in pregnancy. Two of the 27 cases analyzed by Valleix exemplified this fact. It may be caused by a contusion received on the epigastrium. Irrespective of its occurrence as a symptom of gastritis, yellow fever, purpura hemorrhagica, or scorbutus, gastrorrhagia occurs oftener in females than in males. Of 72 cases analyzed by Dr. H. Bence Jones, 53 were females and 19 males, a proportion of nearly 3 to 1.

[1] *Vide* p. 246.

In 40 of these cases the existence of gastric ulceration was more or less certain, and in 32 cases the existence of gastric ulceration was more or less doubtful.[1] It is a rare event in newly-born children, occurring a few hours after birth, the blood being vomited and also passed from the bowels. It proves fatal in some of these cases.

The prognosis, in cases of gastrorrhagia, will depend upon its pathological import. The prognosis is, of course, unfavorable if it be associated with carcinoma, ulcer, or cirrhosis of the liver. If, however, the hemorrhage be vicarious, or not connected with any appreciable morbid conditions, the prognosis, as a rule, is favorable. The loss of blood, in proportion as it is considerable or large, induces debility, anæmia, and it may prove the direct cause of death. In a case which came under my observation in consultation with my colleague, Prof. McCready, the patient, a young married female, was seized with gastric hemorrhage when apparently in good health, and the fatal result, which took place in two or three days, seemed to be attributable to the loss of blood. The amount and rapidity of the hemorrhage may be such as to induce sudden death from syncope. On the other hand, a supplementary hemorrhage, if moderate, is not only without danger, but may conduce to the welfare of the system, so long as the menstrual discharge remains suppressed. In determining the amount of hemorrhage, it is to be borne in mind that the quantity of blood vomited is not always a criterion. The blood may accumulate and coagulate within the stomach without being vomited. The hemorrhage may be sufficient to destroy life, although the quantity vomited be not large. Death may take place in such cases as in cases of concealed uterine hemorrhage. The evidence of hemorrhage out of proportion to the amount of blood vomited, is afforded by dulness of percussion over the distended stomach, and symptoms denoting loss of blood, viz., feebleness of the pulse, coldness of the surface, pallor, faintness, etc. The blood thus accumulating within the stomach, if not vomited, passes into the intestines and is discharged by stool. Hemorrhage into the stomach has been known to occur and death take place from the loss of blood without any vomiting. Grisolle cites three examples, one of which was under his own observation.[2] The stomach in this case was distended with an enormous clot. The diagnosis, when vomiting does not occur, must rest exclusively on the physical evidence of distension of the stomach by a liquid or solid, conjoined with the general symptoms denoting internal hemorrhage.

The treatment of gastrorrhagia has been already referred to in connection with gastric ulcer. The general principles of treatment having reference to the arrest of the hemorrhage, or the prevention of its recurrence, are the same under whatever circumstances it occurs. With reference to these objects, quietude of body and mind is important. Repose of the stomach should be secured by the introduction of no more aliment than the wants of the system require, and the food taken should be bland and easy of digestion. In cases in which there is danger from the amount of hemorrhage, entire rest of the stomach is essential, the system being supported by nutriment and stimulants administered *per enema*. Opium is useful by quieting the peristaltic movements of the stomach. The direct refrigerant effect of iced water taken in small quantities at a time, or of swallowing small pieces of ice, will be likely to be useful. In urgent cases,

[1] *Vide* Med.-Chir. Transactions, published by the Medical and Chirurgical Society of London, vol. xxv., 1860.

[2] Pathologie Interne, tom. ii.

as a temporary means of arresting the hemorrhage, ice may be applied to the epigastrium. In less urgent cases, revulsive measures may be relied upon, viz., sinapisms and dry cups, applied in different situations over the abdomen. Hot, stimulating footbaths are useful by way of revulsion. Hæmostatic remedies are to be given, taking care not to provoke vomiting by their use. The acetate of lead, tannic or gallic acid, and the astringent preparations of iron (the persulphate or pernitrate) are the most efficient of the remedies of this class. The ergot has been supposed to be useful as a styptic in cases of gastric hemorrhage. Emetics are certainly not rationally indicated, except in cases in which percussion furnishes evidence of the stomach being filled with a coagulum, and their propriety may be doubted even under these circumstances. Purgatives are contra-indicated so long as measures to arrest or prevent the hemorrhage are required.

These measures are to be graduated, in individual cases, by the urgency with which the arrest or prevention of hemorrhage is indicated. Mild, simple measures are sufficient if the loss of blood be small or moderate. If there be ground for regarding the hemorrhage as vicarious, interference will be required only to keep it within proper limits. This statement will also apply to hemorrhage occurring in pregnancy.

The treatment in most cases of gastrorrhagia, of course, embraces other measures than those having reference to the arrest and prevention of the hemorrhage, viz., measures addressed to the morbid conditions with which the hemorrhage is associated. The latter are considered under other heads. So, also, measures called for after the occurrence of gastric hemorrhage, having reference to debility and anæmia dependent on the loss of blood, need not be here considered. After a considerable hemorrhage, the stomach, assuming the non-existence of cancer or ulcer, is enfeebled, and the liability to a recurrence of the hemorrhage is to be kept in view. Careful regulation of the diet, quietude of the body, and the avoidance of all disturbing agencies, are important during convalescence.

Gastric hemorrhage is sometimes simulated by hysterical females, and by malingerers among soldiers and prisoners. Blood obtained from animals, and even human blood, may be taken into the stomach, and vomiting excited by various means. This deception may be suspected in the case of a young female who manifests a morbid disposition to impose on the credulity of those around her, as regards her ailments, when the symptoms do not denote loss of blood, when there are no grounds, aside from hemorrhage, to suspect gastric ulcer, and when the menses are not suppressed. Among soldiers and prisoners, it is to be suspected when the usual effects of hemorrhage are not apparent, and when the morbid conditions with which gastric hemorrhage is usually associated are wanting. The microscope may be of use in the detection of this kind of deception. Bennett cites a case in which a specimen of blood, which it was pretended had been vomited, was found to present the characteristic red corpuscles of the blood of a bird.

CHAPTER VI.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINES.—(Continued.)

Inanition. Gastralgia. Passage of Gall-Stones. Diarrhœa. Enterorrhagia.

IN addition to the ailments embraced under the head of dyspepsia are various functional affections of the stomach and intestines. These will be considered in the following order: Gastralgia, including gastric spasm, and, in this connection, the passage of gall-stones, or hepatic colic, may be most conveniently considered; diarrhœa, and hemorrhage from the bowels, or enterorrhagia; enteralgia and the affections known as saturnine or lead colic; sporadic and epidemic cholera.

Before entering upon the consideration of the affections just enumerated, I will offer a few remarks on a pathological condition which is not, perhaps, entitled to rank in the nosological catalogue as an individual disease, but which is an element of all diseases compromising alimentation and digestion. The pathological condition referred to is *inanition*. The importance of a due appreciation of this condition in medical practice renders it desirable to devote to it some attention, and it may with propriety be noticed in connection with the functional affections of the alimentary canal.

INANITION.

Health requires the assimilation of nutriment adequate, in quantity and kind, to the wants of nutrition. Every one is familiar with the mental and physical exhaustion felt when abstinence is protracted for a few hours only after the sense of hunger indicates the need of food. Every one knows that the deprivation of aliment, for a period varying according to circumstances, proves fatal. During the progress of starvation, the body loses rapidly in weight, the fat disappears, the muscles diminish in size, exhaustion progressively increases, the heat of the body is notably lowered, vomiting and diarrhœa not infrequently occur, the mental powers are weakened, listlessness and hebetude are sometimes followed by delirium and coma, and, according to Chossat, if the deprivation of aliment be complete, death takes place when one-fourth of the weight of the body at the time aliment was withheld has been lost. The mode of dying is a type of slow asthenia. It is worthy of note that, during the progress of starvation, hunger is not usually a prominent symptom. If felt for a time, it is apt to disappear, and may be followed by a loathing of food. Our knowledge of the natural history of inanition in man is derived chiefly from cases in which starvation is unavoidable, as in times of famine, in shipwreck, or when it is resorted to for self-destruction. Under these circumstances, however, the phenomena due to the want of nutriment are apt to be more or less modified by extrinsic circumstances. Experiments made on inferior animals are unsatisfactory because the symptoms can be but imperfectly appreciated. The best source of information is voluntary abstinence for the purpose of scientific observation. As a near approach to experiments of this kind, those made by Hammond to test the nutritive

value of albumen, starch, and gum, may be cited.[1] Submitting himself to the trial of restricting his diet to these alimentary principles singly, Hammond found that each is incapable alone of supplying the wants of the system, and that the two latter are absolutely innutritious. Now, the morbid phenomena produced during these experiments are to be considered as resulting from the absence of aliment; in other words, they were due to starvation. So far as they go, therefore, these experiments serve to exemplify the symptomatology of inanition. Referring the reader to the work by Hammond for fuller details, I will simply enumerate here the more important of the symptoms which he experienced.

1. Under a diet consisting of pure albumen for ten days: Febrile movement, heat and dryness of skin, headache, loss of appetite, nausea, abdominal pains, progressively increasing debility, serious diarrhœa, vigilance.

2. Under a diet of pure starch for ten days: Debility, disturbed sleep, sense of oppression of chest, palpitation, headache, slight scratches of the skin showing tendency to inflammation and suppuration, febrile movement, abdominal pains.

3. Under a diet of gum, which he was able to continue only for four days: Abdominal pains, disturbed sleep, headache, febrile movement, diarrhœa, exhaustion.

Inanition is a pathological condition entering into all diseases which interfere with the ingestion or the assimilation of aliment. The phenomena of inanition in cases of these diseases are combined with the symptoms belonging to the particular disease which exists. Febrile movement, headache, anorexia, vigilance, delirium, debility, etc., occurring in the progress of a disease, arise, not exclusively from the disease *per se*, but are more or less due to inanition. The inability of the system to support, resist, and overcome disease proceeds, in a greater or less degree, from this element. The immediate cause of death in many cases of disease proving fatal by slow asthenia is inanition. These are facts of very great practical importance, and they are not sufficiently appreciated by many practitioners of medicine.

An important practical bearing of these facts relates to alimentation in the management of diseases. Until recently, for many years past, not only has the importance of alimentation not been fully recognized in practice, but in most diseases the dietetic treatment has contributed to inanition. The writings of Graves led to the employment of alimentation in fevers. It is not less important in all other diseases which tend to destroy life by asthenia. Patients may be starved to death in other diseases as well as in fevers. As a practical rule, it is an object in any disease in which the danger lies in the direction of asthenia to meet, as far as practicable, by alimentary supplies, the wants of nutrition. Harm may arise from the ingestion of food beyond the powers of digestion, but, in these diseases, no harm can arise from an undue assimilation of food; on the contrary, the greater the assimilation the less the danger from inanition superadded to the disease. Let it be borne in mind that, in all diseases tending to destroy life by asthenia, there is danger from inanition, but never from hyper-nutrition. In the language of Chossat, "inanition is a cause of death which marches silently in front with every disease in which alimentation falls below the normal standard. It reaches its natural termination sometimes sooner and sometimes later than the disease which it covertly

[1] *Vide* Physiological Memoirs, by Wm. A Hammond, M.D., Surgeon-General U. S. Army, etc., 1863.

accompanies, and it may supersede the disease of which at first it was merely an incidental element."[1]

Alimentation is important in diseases not attended with immediate danger. In proportion as the assimilation of food can be made to approximate to the normal standard, the phenomena of inanition are forestalled, the vital powers are better enabled to tolerate and overcome the disease, the duration of the disease may be shortened, convalescence is hastened, and the recovery is more apt to be complete. As regards the selection of food and the modes of its preparation in different diseases, in addition to dietetic rules based on general experience, our knowledge of alimentary principles, etc., much reliance may generally be placed upon the desires and tastes of the patient; but the absence of appetite is not to be a guide as regards alimentation. Loss of appetite is one of the symptoms of inanition. The wants of the system are not in disease, as in health, always expressed by hunger. The state of the mind dependent on the morbid condition of the nervous system, the coatings on the tongue, etc., interfere with the desire for food and the sense of taste. The practitioner is to exercise his judgment and tact in securing, as far as practicable, the assimilation of an adequate amount of nutriment either with or without the co-operation of desire and taste on the part of the patient, and it is often better to incur risk of exceeding rather than falling below the amount of food which the wants of the system require. It may be laid down as a principle applicable to the management of most acute diseases, that the assimilation of food is important to the fullest practicable extent; and it is a maxim of conservative medicine that, under all circumstances, a chronic affection is less likely to be prolonged, serious lesions of structure are less liable to take place, and a fatal termination is postponed, in proportion as the vital powers are maintained by a nutritious diet conjoined with other hygienic measures.[2]

Innutrition is not infrequently involved in the causation of diseases. The connection between scarcity of food and the prevalence of typhus has been repeatedly observed in epidemics in Ireland. The same connection in individual cases and families is observed frequently everywhere. Scorbutus is caused by a deficiency of certain alimentary principles, or the want of a sufficient variety in food. Insufficient nourishment, which is sometimes involuntary and sometimes voluntary, favors the development of tuberculosis in persons having the tuberculous diathesis. This cause may co-operate with other causes in giving rise to various diseases, whether epidemic or sporadic; and the ability of the system to bear up under disease is impaired in proportion as the powers of life are enfeebled by previous defective alimentation.

Want of success in the treatment of diseases in hospitals and often in private practice, especially among the poorer classes of society, is attributable, in no small measure, to the want of effective alimentation.

GASTRALGIA.

Gastralgia, called frequently gastrodynia, is a neuralgic affection characterized by pain, more or less intense, referred to the region of the stomach. Pain is a symptom of gastritis, carcinoma of the stomach, and gastric ulcer;

[1] Recherches Expérimentales sur l'Inanition, Mém. de l.Acad. des Sciences, 1843.

[2] *Vide* essays on *Conservative Medicine*, by the Author, American Journal of the Medical Sciences, January and October, 1863. *Vide*, also, essay on alimentation in disease, New York Med. Journal, 1867.

it also enters into the clinical history of dyspepsia, especially the variety called acute dyspepsia, and a peculiar character of pain constitutes the dyspeptic symptom called cardialgia, or heartburn. But, considered as characterizing a distinct functional affection, the pain is not incidental to inflammation or any appreciable lesion, nor is it always, although frequently, associated with dyspeptic disorder; in short, gastralgia exists when pain and other circumstances denote an affection of the same pathological character as neuralgia in other situations.

Gastralgia is presented in practice in two forms; in one form a severe attack of pain occurs, and, if not relieved by remedies, continues for several hours or even days. The pain is often excruciating, subduing the strongest resolution; the patient writhes and groans with intense suffering. A sense of constriction frequently accompanies the pain; vomiting may, or may not, occur. Generally, tenderness over the epigastrium is wanting, and some relief may be afforded by pressure. The paroxysm is not attended with febrile movement, and the skin may be bathed in perspiration from the intensity of pain. These attacks are generally attributed to spasm or cramp, and the affection has been called colic of the stomach. It is difficult to say how much of the suffering is due to spasmodic contraction, and how much to neuralgic pain. Practically, it is not important to make this discrimination.

Such attacks in some persons are produced by certain ingesta. Strawberries, for example, have been known to prove in this way poisonous, and I have met with a patient who had always an attack after eating honey; he came under my observation when suffering from an attack thus produced. These, like other idiosyncrasies, are inexplicable. Attacks appear to be sometimes attributable to exposure to cold, and fatigue from overexertion.

This form of gastralgia is readily discriminated from acute gastritis. The pain may be much more intense than in cases of the latter disease. As a rule, the tenderness over the epigastrium which belongs to the history of gastritis, is wanting. Vomiting may be wanting, and, if present, is not as prominent a symptom as in gastritis. The absence of febrile movement is an important point in the exclusion of gastritis. The passage of gall-stones, or hepatic colic, offers many symptoms in common, and this discrimination is not at once readily made. The points involved in the differential diagnosis will be considered presently, in treating of the passage of gall-stones.

This form of gastralgia is to be treated by opiates carried to the extent of procuring relief. A half grain of a salt of morphia may be sprinkled on the tongue, and this dose repeated, if necessary, after the lapse of from half an hour to an hour, until the pain is relieved; or the same course may be pursued with other forms of opiate. If the opiate be rejected from the stomach, it may be given *per enema*. The hypodermic mode of administration is well suited to this, as also to other affections in which it is desired to produce quickly and efficiently an anodyne effect. This plan of treatment is not to be deferred for the operation of a cathartic, or an emetic, even when the attack is attributable to a dietetic cause. A sinapism, and fomentations to the epigastrium are useful as auxiliary measures. An alcoholic stimulant may be added with advantage, if not contra-indicated by vomiting, especially if the pulse be feeble and the surface cold. Rest, regulated diet, and a mild cathartic or laxative, provided the bowels do not act spontaneously, will constitute the subsequent treatment.

Although the suffering is as great as in any other affection, there is little or no danger. It may be doubted whether this affection, alone, ever proves

fatal; and the practitioner may count with confidence on procuring speedy relief by means of the plan of treatment just stated. The affection, therefore, is one of those which exemplify, in a striking manner, the resources of medicine.

The foregoing form of gastralgia may be distinguished as *acute*. In the other form, the affection becomes *chronic*. The pain, in the latter, is either limited to paroxysms which recur more or less frequently, or it is habitual, with exacerbations at variable intervals. The pain varies much in different cases, as regards intensity, and also in different paroxysms or exacerbations in the same case. It may have so little intensity as to occasion only annoyance, or it may be so severe as to give rise to extreme suffering. The character of the pain is described by patients as burning, lancinating, or gnawing. Frequently the pain extends from the epigastrium in different directions, viz., to the back, into the chest, and, laterally, into the right and left hypochondrium.

With the affection, in some cases, are associated dyspeptic ailments, and in other cases, digestion is not disturbed. Paroxysms or exacerbations sometimes appear to be provoked by the ingestion of food, but as a rule, relief of pain is felt after eating. The desire for food is oftener increased than diminished. Generally, tenderness over the epigastrium is wanting, and pressure frequently affords relief. The decubitus during suffering from pain is sometimes upon the belly. Constipation exists much oftener than looseness of the bowels. Flatulent distension of the stomach or intestines is sometimes associated. The pulse preserves its normal frequency, and the temperature of the body is not increased. Patients who have suffered from the malady for some time are apt to become melancholy and hypochondriacal. I have known it to be associated with a tendency to suicide.

Gastralgia rarely, if ever, occurs under the age of puberty, or in old age. The average age, according to Barras and Valleix, is about thirty-two. It is generally considered that females, much more than males, are liable to it, but of 39 cases analyzed by Valleix, only 20 were females. It affects those of good constitution and the robust, as well as the feeble and delicate. Persons of sedentary habits appear to be more likely to be affected than those engaged in active pursuits. Prolonged mental depression has been supposed to favor its occurrence. Prof. Alfred Stille states that chewing tobacco is one of the most frequent of causes. It appears in some cases to depend on the gouty diathesis. Like neuralgia in other situations, it may be an effect of malaria; and attacks of gastralgia may recur with the regularity of the paroxysms of intermittent fever. I have known gastralgia to take the place of the cold stage of paroxysm, being followed by the hot and the sweating stage. Finally, causes which induce anæmia or lead to debility, may be more or less involved in its production.

The diagnosis of the chronic form of gastralgia is to be based on certain distinctive characters, viz., the occurrence of pain either in paroxysms or marked exacerbations; the relief frequently afforded by pressure and the ingestion of food; the persistence of appetite in many cases, and, not infrequently, the absence of disorder of digestion, and the absence of febrile movement. These points in the history are involved especially in the discrimination of gastralgia from subacute or chronic gastritis. The diagnosis involves the exclusion of gastric ulcer and cancer. These affections are to be excluded by the absence of their diagnostic symptoms, irrespective of pain. In some cases of intercostal neuralgia, pain is referred to the epigastrium. This affection is excluded by the absence of its diag-

nostic criterion, viz., tenderness on pressure over three points—posteriorly, laterally, and anteriorly.[1]

Chronic gastralgia is apt to be persisting. Its duration, in different cases, is extremely variable. In this respect it resembles other neuralgic affections. Of thirty-nine cases analyzed by Valleix, in one case the affection lasted for twenty-six years, and the patient, at the end of this period, was carried off by another disease. In the remainder of the cases, the duration varied from two months to twelve years. As regards prognosis, the worst to be apprehended is the indefinite protractedness of the affection. It does not tend to destroy life either directly or by eventuating in some other more serious disease. It is not prudent for the practitioner to predict that the affection will end speedily, or within any definite period; yet, not infrequently, it does not continue. In certain cases it is one of the affections most rebellious to therapeutical measures, but in other cases it is readily amenable to treatment.

In the treatment of gastralgia, clinical experience has abundantly shown certain measures formerly in vogue to be not only ineffectual but prejudicial. This remark has reference to general and local bloodletting, emetics, mercurials, purgative remedies, and perhaps also vesication or other modes of active counter-irritation. Anodyne remedies are frequently called for to relieve pain. If the pain be severe, opium can hardly be dispensed with; but in this, as in other painful affections which are apt to be persisting, the liability to the formation of a habit of using opium is to be considered. Moreover, the use of opium, aside from the palliation of pain, is objectionable on account of its interference with the appetite and digestion, and, in this way, it may contribute to perpetuate the affection. Opium is, therefore, to be used with circumspection, and, when practicable, other palliative measures are to be substituted, such as belladonna, hyoscyamus, etc. Fomentations and embrocations containing opium, chloroform, aconite, etc., will sometimes succeed in affording relief. Cold water applied to the epigastrium has been found effectual. Certain remedies appear, in some cases, to exert a curative influence. Bismuth is one of these. I have known large doses of this remedy to be promptly curative. Monneret advises this remedy to be given to the extent of one, two, or three ounces daily. These enormous doses are not required. Whatever curative power the remedy has will be exerted in doses of from a scruple to a drachm three or four times daily. Alumen has been recommended by Dr. Griffin in doses of from ten to twenty grains three or four times daily.[2] Strychnia and the nux vomica have been found useful, especially if the affection be associated with the formation of gas. A quarter of a grain of the watery extract of nux vomica may be given three or four times daily. Other remedies which may be employed with a view to a curative effect are the nitrate of silver, quinia in full doses, the subcarbonate of iron (precipitated carbonate or sesqui-oxide) given in drachm doses, the iodide of potassium, and arsenic, as in other neuralgic affections. Dr. Leared, of Dublin, has employed with much success the purified oxide of manganese in doses of from five grains to half a drachm three times daily.[3]

Measures of treatment, other than the employment of direct curative remedies, are of greater importance than these. Change of habits from those of sedentary to active life is of the first importance in certain cases. The moral influence of recreation, change of scene, etc., is often of more

[1] *Vide* page 202. [2] Stillé's Therapeutics, vol. i. page 191.
[3] Dublin Medical Press, 1865.

value than medicines. The diet should be nutritious. Alcoholic stimulants in moderation with meals may be advised for a time, exercising that reserve dictated by the danger of patients becoming addicted to their habitual use. Tonic remedies, in most cases, continued steadily for a long period, and varied from time to time, are advisable. The valerianate of zinc may be mentioned as a tonic remedy likely to prove useful. Preparations of iron are especially indicated if anæmia be present. Dyspeptic ailments, which may be associated, are to receive appropriate treatment. In short, the object, aside from the employment of palliative and curative remedies, is to endeavor to place the digestive organs and the system in the best possible condition, and, for this end, hygienic and medicinal measures are to be adapted to the circumstances peculiar to individual cases.

PASSAGE OF GALL-STONES.

The passage of biliary calculi along the cystic and common duct may give rise to symptoms resembling those of acute gastralgia. The discrimination, at once, is not always easy. Moreover, a paroxysm of pain from the passage of a gall-stone, or hepatic colic, as it has been called, is to be discriminated from affections other than gastralgia, viz., peritonitis, ordinary colic, colic with intestinal obstruction, acute gastritis, and the passage of calculi from the kidney to the bladder. Biliary calculi usually form in the gall-bladder, but cases have been reported in which they have been found in the hepatic duct and its branches within the liver. They vary in size from that of a pin's head to that of a hen's egg. They are frequently found in the gall-bladder after death, and sometimes in great number. A collection of several hundred is not uncommon. Bennett relates a case in which the number amounted to two thousand, and cases have been reported in which the number was still greater. They are usually of soft consistence, and of a low specific gravity. They are sometimes white, but oftener either of a yellow, brown, or greenish color, from the imbibition of bile. On section they are often found to consist of successive layers which differ in consistence and color. In general they are composed chiefly of cholesterin, but they frequently contain the salts of lime. Remaining within the gall-bladder, they may occasion no inconvenience; but, if very numerous or large, they may give trouble by distending the gall-bladder, and they may lead to ulceration and perforation. If the perforation be into the peritoneal sac, peritonitis follows, and will be likely to prove fatal. If the distended gall-bladder become adherent to the abdominal walls, the perforation may lead to a circumscribed abscess which opens externally, and numerous calculi may be discharged through the opening. Prof. James P. White has reported an interesting case of this kind.[1] They are also sometimes discharged by an ulcerated opening into the intestinal canal. The presence of gall-stones within the gall-bladder has been determined by means of a characteristic sound, resembling the collision of nuts or marbles in a bag when shaken, produced by forcible pressure or strong percussion over the distended bladder. But, in general, their existence is not suspected until, having entered the cystic or common duct, they occasion, by their passage toward the intestine, paroxysms of so-called hepatic colic. It is evident that the time occupied in the passage of a gall-stone, and the suffering, will depend, other things being equal, on its size and the irregularity of its shape.

[1] Buffalo Medical and Surgical Journal, June, 1864.

The pain occasioned by the passage of a gall-stone is frequently abruptly developed without any obvious cause, but in some cases it is preceded by a sense of uneasiness referred to the right hypochondrium. In the majority of cases the attack occurs three or four hours after a meal. The suffering is often extreme, causing the patient to writhe, and try a variety of positions with the hope of obtaining relief. The pain is referred to the epigastrium or the right hypochondrium. It may radiate thence throughout the abdomen, often extending into the chest, and to the right shoulder. Usually there is more or less tenderness over the seat of the pain, but in some cases pressure affords a certain measure of relief. Vomiting speedily occurs in the majority of cases, and is repeated more or less frequently during the continuance of the pain. The bowels are constipated. The pulse, as a rule, is not accelerated, and it may be retarded; not infrequently it becomes small and weak. The retardation of the pulse is sometimes notably great; I have known it to fall to 30 and 20 beats per minute. Pallor of the face and coldness of the surface are marked in some cases. Chilly sensations, with rigor, are not uncommon. These symptoms are sometimes so marked as to suggest the existence of malarial disease. The duration of the paroxysm is variable; it may last for a few moments only, or for many hours, depending, of course, on the period occupied by the passage of the stone either onward into the intestine or backward into the gall-bladder. At length, the pain and other symptoms suddenly cease, and nothing remains but more or less soreness and the fatigue occasioned by the suffering. If the paroxysm have been of considerable duration, the urine may show the presence of bile, and jaundice is frequently produced. These symptoms disappear after the paroxysm is ended. If dejections occur, they may show deficiency or absence of bile. The resorption of bile, and its absence in the stools, show that the gall-stone is impacted in the common, not the cystic, duct, and that its form and size are sufficient to cause obstruction more or less complete. Under these circumstances, the bile may accumulate within the gall-bladder, and distend it so that it can be perceived by the touch below the lower margin of the liver. Finally, after the paroxysm is ended, one or more gall-stones may be discovered in the dejections if these be carefully examined. In some cases, however, careful examinations of the feces fail to show the presence of a calculus, or of calculi. The failure to discover them is not proof that an attack of hepatic colic has not been experienced, for the gall-stones, in these cases, after remaining for a time in the cystic duct, may have passed backward into the gall-bladder.

When one attack has been experienced, recurrences are to be expected, but, as regards the intervals, cases differ greatly. Successive attacks may occur after days, weeks, months, or years. Not infrequently, numerous attacks are experienced in quick succession, several, perhaps, occurring in the same day, and for several days in succession. This is probably owing to the temporary dilatation of the cystic and common duct produced by the passage of calculi of considerable size, in consequence of which other stones within the gall-bladder more readily escape. The patient, under these circumstances, may be consoled by the reflection that the more frequent the passage of calculi, the less are the number remaining to give rise to subsequent attacks; provided, of course, they pass through the common duct into the duodenal cavity. The frequent repetition of attacks, if severe, may occasion considerable disturbance of the digestive system, and general prostration.

The differential diagnosis of the passage of gall-stones from acute gastralgia is to be based on the following points: The occurrence of pain,

not excited by any obvious dietetic or other cause; the prominence of vomiting as a symptom; the presence, generally, of more or less tenderness; the existence of bile in the urine, and of icterus or an icterode hue of the conjunctiva and skin; retardation of the pulse; the persistence of pain, notwithstanding opiates are given in full doses; the sudden relief occurring irrespective of remedies; and, after the attack, the discovery of biliary calculi in the evacuations.

The examination of the evacuations for gall-stones not only serves to establish the diagnosis, but, on the appearance of the stone, or stones, may be predicated an opinion that the gall-bladder does, or does not, contain calculi which have not escaped. If a single round or oval stone only be discovered, it is probable that this was a solitary calculus in the gall-bladder, and other attacks need not be expected; but if several stones are discovered, polyhedral in form, with smooth or polished facets, which may be plane, convex, or concave, it is highly probable that the gall-bladder contains others, and the patient cannot count on being exempt from repetitions of the paroxysms produced by their passage. The most effectual mode of examining for the presence of stones is to dilute the feces and strain through a sieve.

Acute peritonitis may be accompanied by pain, resembling in intensity that of hepatic colic. But, in determining the existence of the latter, peritonitis is to be excluded by the absence of tenderness diffused over the abdomen, of rigidity of the abdominal walls, of tympanitic enlargement, of the notable acceleration of the pulse, together with the general prostration which belongs to the clinical history of peritoneal inflammation. Peritonitis, however, may proceed from perforation of the biliary canal, caused by persisting impaction of a gall-stone. In cases of ordinary colic, the pain is more paroxysmal, with intervals of freedom from pain. Invagination and internal strangulation of the intestine are to be excluded by the absence of a tumor caused by the accumulation of the intestinal contents at the point of obstruction, by the absence of obstruction, and of acceleration of the pulse, together with the greater gravity of the general symptoms in those affections. In acute gastritis, vomiting is a more prominent symptom than in hepatic colic, and the greater gravity of the affection is shown by the pulse and other general symptoms. In some cases of hepatic colic, the pain extends downward in the direction of the right ureter, so that the passage of a calculus along this duct may be suspected. The absence of certain symptoms belonging to the history of so-called nephritic colic, viz., retraction of the testicle, deficiency of the urine, hæmaturia, etc., will serve to exclude this affection. Knowledge of the occurrence of one or more prior attacks which have been ascertained to be due to the passage of gall-stones, will aid in determining the diagnosis. The age of the patient is of some account in the diagnosis. Gall-stones may form at any age, but they are most apt to form in middle or advanced life, and in females oftener than in males.

In the great majority of cases, gall-stones, escaping from the gall-bladder, find their way into the intestine, giving rise to no evil results beyond the pain, etc., which their passage occasions. But occasionally a stone becomes permanently impacted in the biliary canal, and, if situated in the common or hepatic duct, retention of bile ensues, giving rise to persisting cholæmia, and softening of the liver from the distension of the bile-ducts. Under these circumstances, ulceration and perforation of the duct are liable to take place, leading to peritonitis; or adhesive circumscribed peritonitis may have preceded the perforation, and, the latter extending through the intestinal coats, the stone may be discharged into the intes-

tine or through the abdominal walls. Obliteration of the canal of the common duct, as a result of inflammation and ulceration excited by the presence of the stone, sometimes occurs.

The rationale of the formation of gall-stones is not understood. Probably the deposit in a solid form of certain of the constituents of bile takes place in consequence of the presence in the biliary passages or gall-bladder of mucus, collections of which are the nuclei for the formation of calculi. Hence gall-stones may be the result of inflammation of the gall-bladder or ducts. It has been conjectured that cholesterin may be deposited in consequence of the bile losing the faculty of holding this principle in solution from a diminution of the tauro-cholic acid. It is not improbable that an excess of the salts of lime or of bile pigment may lead to the production of nuclei.

The treatment of a paroxysm of hepatic colic consists of palliative measures. Opiates are called for in doses proportionate to the intensity of the pain, either administered by the mouth or rectum, or hypodermically. The degree of suffering, in some cases, is such that the inhalation of chloroform is warrantable as a palliative measure. Warm anodyne fomentations may be applied to the seat of pain. The hot bath may aid in procuring relief. The local application of cold by means of a bladder filled with pounded ice, has been found to be useful as a palliative measure. Remedies to palliate vomiting are frequently called for. Effervescing draughts and the hydrocyanic acid may be employed for this purpose. An alkaline remedy may be found useful, if, as is frequently the case, the matters vomited show notable acidity of the stomach. The foregoing palliative measures will alleviate the suffering, but it is not to be expected that they will procure complete relief.

Emetics and catharties have been advocated under the notion that they aid in the passage of the stone. It is irrational to suppose that they have this effect, and clinical observation does not furnish evidence of their value. The passage of the stone is mainly due to the accumulation of bile behind it after it enters the common duct, conjoined with contraction of the muscular coat of the gall-bladder. Exciting the movements of the stomach and intestines by emetics and cathartics, if any effect be exerted, is as likely to retard as to favor the onward passage of the stone. Nothing, in fact, can be done by means of these or other remedies to expedite its passage. All that the physician can do is to palliate suffering until the stone is propelled into the intestinal canal, supporting the strength, if need be, by alcoholic stimulants. If, however, the distended gall-bladder form a tumor which is appreciable by the touch, an effort may be made, by pressure with the fingers, to propel the bile in the ducts, and thus aid in the removal of the obstruction.

It would be desirable, if possible, to effect the solution of gall-stones within the gall-bladder. The alkaline carbonates have been given for this purpose; and the treatment for this end, known in France as Durande's method, consisting of the administration of sulphuric ether and the spirits of turpentine (3 parts of the former to 2 parts of the latter), was for some time in vogue. Dr. T. H. Buckler[1] has proposed the use of chloroform in view of the solvency of cholesterin in this liquid. He has reported a case in which an indurated tumor felt through the walls of the abdomen directly over the inferior margin of the liver disappeared in five days under the use of chloroform given in teaspoonful doses after each meal. It was concluded that the tumor was the gall-bladder distended with calculi; but

[1] American Journal of Medical Sciences, July 1867, p. 51.

there is room for doubt as to the correctness of this diagnosis. It seems hardly probable that any remedies can be introduced into the system so as to enter into the composition of the bile largely enough to dissolve the cholesterin of which mainly biliary calculi are composed.

The occurrence of gall-stones cannot be anticipated, but, being known, it is, of course, desirable to prevent the formation of others. The circumstances, however, immediately concerned in their production, are not known; hence, there is no special course of treatment rationally indicated, and clinical experience is not to be relied upon, since the success of preventive measures cannot be proven. It would seem that sedentary habits predispose to them. A change, in this respect, is therefore advisable. Beyond this, a simple, wholesome diet, and measures having reference to the general health, constitute all that can be done, with our present knowledge, in the way of prophylaxis. Dr. Buckler suggests the hydrated succinate of the peroxide of iron in cases in which gall-stones are known to have been passed, the object being to prevent their further formation; this remedy, as he supposes, controlling the fatty or cholesteric diathesis.[1]

Gall-stones of sufficient size to occasion intestinal obstruction, are sometimes found in the alimentary canal. These escape from the gall-bladder, not through the biliary passages, but by ulceration, the walls of the gall-bladder becoming adherent to the duodenum, or some other portion of the intestine. Dr. Henry F. Walker has reported an interesting case in which a gall-stone presenting the form of an elongated gall-bladder, measuring in the long diameter $3\frac{1}{2}$, and in the short diameter $1\frac{1}{4}$ inches, was removed from the rectum. The previous history, in this case, showed peritonitis, which probably denoted the time when the stone was making its way from the gall-bladder into the intestinal cavity, and, afterward, intestinal obstruction with alarming symptoms. These symptoms suddenly ceased, the probable explanation being that the stone passed, at that time, from the small into the large intestine.[2]

A patient who consulted me, having suffered much from the passage of gall-stones, at one time took, for a number of days, a pint or more of olive-oil daily, at the suggestion of some one who assured him that, in this way, he had gotten rid of a large number of stones without pain. The patient stated that, under the use of this remedy, he discharged from the bowels an immense number of small hard bodies, which were supposed to be biliary calculi. These are not scybalæ, that is, masses of fecal matter, but they are composed of a concrete form of fatty matter like the bodies passed in some of the cases of fatty diarrhœa which have been reported. A case is quoted by Dunglison, in which olive-oil, taken abundantly for the relief of pains attributed to gall-stones, was followed by the discharge of fatty matter of a globular form, varying in size from that of a small pea to that of a moderate grape, of sufficient consistence to bear being cut with a knife like soft wax.[3]

[1] This remedy is given by Dr. Buckler as follows: Hydrated succinate of the peroxide of iron, ℥iss; water, f℥viss. A teaspoonful after each meal, continued for several months; and resumed at intervals afterward. In his article Dr. B. stated that at that time (1867) the salt was prepared only by Dr. David Stewart and his brother, J. V. D. Stewart, of Baltimore.

The student is referred to "A Treatise on Gall-Stones," by J. L. W. Thudicum, M.D., London, 1863, for a full consideration of their chemistry, pathology, and treatment. *Vide*, also, Murchison's Clinical Lectures on Diseases of the Liver, etc.

DIARRHŒA.

The term diarrhœa is used to denote morbid frequency of the dejections which are, also, liquid or morbidly soft, and often otherwise altered in character. Diarrhœa is a symptom of inflammation of the large and small intestine, and of certain structural lesions, such as those incident to tuberculosis of the intestine and to typhoid fever. It is a functional affection when it occurs independently of inflammation or any appreciable lesion of structure. It is an element of other functional affections, viz., sporadic cholera, dyspepsia, and certain cases of colic. As a functional affection, it may be either transient or chronic.

Writers have made numerous varieties of diarrhœa, based on diversities as regards the character of the dejections. It is sufficient to enumerate the more important of these diversities without considering each under a distinct head, as constituting a separate variety of the affection. The following division answers all practical purposes:—

A diarrhœa is said to be *fecal*, *feculent*, *stercoraceous*, or *simple*, when the dejections consist of the feces not much changed in character, but simply morbidly soft or liquid. This form of diarrhœa is represented by the operation of cathartics which increase the peristaltic movements and give rise to a certain amount of transudation. The dejections in this form of diarrhœa have the normal fecal odor. The dejections are called *bilious* when, from their yellow or green color, bile is supposed to be present in larger quantity than usual. Diarrhœa of this kind is represented by the operation of calomel in cathartic doses. The yellow color of the discharges, however, which characterizes the so-called bilious stools, is due to secretions from the mucous membrane of the large intestine, inasmuch as the contents of the small intestine do not present this color. The green color which has been considered so characteristic of the action of mercury upon the liver, according to Thudicum, is due to the presence of the subsulphide of mercury.[1] Robin, however, states that the microscope shows the coloring matter to be biliverdin.[2] Diarrhœa is *serous* or *watery*, when there is an abundant discharge of liquid, that is, when there is copious transudation or enterorrhœa. This is represented by the operation of hydragogue cathartics, such as elaterium, jalap, and the bi-tartrate of potassa. The dejections are called *lienteric* when they contain undigested aliment. This form of diarrhœa is met with more especially in children. A diarrhœa is *catarrhal* or *dysenteric*, when mucus is apparent in the dejections. An abnormal amount of mucus may be secreted from irritation alone, without inflammation, but if the mucus be abundant, it denotes dysentery. This form of diarrhœa is represented by the operation of drastic cathartics, such as croton oil. Finally, in a curious and extremely rare form, called *adipose* or *fatty diarrhœa*, free fat or oil, in more or less abundance, is found in the evacuations. This last form claims some distinct consideration.

In cases of adipose or fatty diarrhœa, the fat is generally liquid when passed, resembling melted butter or grease, having, when cold, the consistence of butter, beef tallow, or wax. In some cases it is passed in the form of globular concretions, of a waxy consistency, varying in size, which melt with heat and burn like tallow. The fat is often passed by itself, and is apt to be passed involuntarily in a small quantity at a time. When passed with the feces, it separates and collects on the surface. It has usually an extremely offensive odor. The quantity passed *per diem*,

[1] London Lancet, Oct. 1860.

[2] *Sur les Humeurs.*

in cases which have been reported, varies from two or three ounces to half a pound or more.

Assuming all the fat passed from the bowels to have been ingested as fat, the rationale involves simply the non-digestion of this alimentary constituent. But in some reported cases it is stated that the quantity of fat passed was not affected by the amount of fatty food. In a case reported by Dr. W. L. Wells, the patient abstained for several weeks from fatty food, and, as far as convenient, from articles convertible into fat, without any diminution in the quantity of fat passed, nor was the latter affected by indulging freely in fatty food.[1] In two cases reported by Bright, no change was produced by excluding, as far as possible, from the diet fatty articles. Further and more precise observations with respect to this point are desirable. That the non-digestion of fat is, in a great measure, if not exclusively, involved in the pathological explanation, is not to be doubted. Late physiological researches have shown that the pancreatic secretion, together with the bile and intestinal juice, effects the digestion of fat, and hence we are to look to the sources of these fluids in tracing the causation of fatty diarrhœa. It is an interesting fact that Richard Bright, long before the late discovery of the particular function of the pancreas by Bernard, was led, by an analysis of three cases which came under his observation, to consider fatty diarrhœa as a symptom of disease of the pancreas. In these three cases, the only lesions found after death which were common to all were of the pancreas, duodenum, and liver. He excluded the lesions in the two latter situations because they occur in these organs so often without fatty diarrhœa, but he admits that disease of the pancreas is not always accompanied by this symptom.[2] The pancreas has been found diseased in a large majority of the reported fatal cases in which this organ was examined after death. Of twenty-five cases tabulated by Dr. John H. Griscom,[3] in ten the bodies were examined after death; of these ten cases, in eight the pancreas was diseased, and in the remaining two cases the absence of disease of the pancreas is not stated. Yet fatty diarrhœa occurs in only a small proportion of the cases of disease of the pancreas. Thus, it was observed in only three of thirty-seven cases of cancer affecting this organ tabulated by Dr. Da Costa.[4] Hence, it is to be inferred that, in connection with disease of the pancreas, lesions or morbid conditions affecting the liquids, other than the pancreatic secretion, concerned in the digestion of fat, are generally involved. Of the fatal cases among those tabulated by Griscom in which the morbid appearances were observed, the liver in several was either diseased or its ducts engorged; but in some of the cases this organ appeared to be healthy. The fact of complete recovery taking place in a certain proportion of cases, goes to show that the non-digestion of fat may occur as a functional disorder.

A larger number of cases than are as yet available are required in order to establish the clinical history, as well as the causation and pathological relations, of this form of diarrhœa. Jaundice was noted in several (six) of Griscom's cases. Diabetes mellitus co-existed in two cases. Hemorrhage

from the bowels, vomiting, pains in the abdomen sometimes resembling those caused by the passage of gall-stones, are among the symptoms noted in these cases. The duration of the affection varies much in different cases. In one case it had existed at frequent intervals for six years; in another case for two years; and in one case it disappeared after a few weeks. It is evident that the prognosis is to be based on circumstances other than the discharge of fat, viz., enlargement of the pancreas and liver, persisting jaundice, progressive emaciation, etc.; in other words, the danger depends on the lesions or morbid conditions on which the discharge of fat may be dependent, or with which it is associated. Of the 25 cases collected by Griscom, 14 died, 8 recovered, and in 3 the termination was not noted.

The treatment must have reference more to the circumstances connected with the fatty diarrhœa than to the latter. With our present knowledge, palliative measures according to the symptoms in individual cases, together with measures to improve digestion and invigorate the general health, will comprise the treatment. In one of Griscom's cases recovery took place under the use of olive oil in large quantity; and Watson states that a case was successfully treated by Elliotson in the same way. In a case observed by Griscom at the New York Hospital, the discharge of fat invariably ceased whenever the patient took from six to eight ounces of whiskey *per diem*. In the case reported by Dr. Wells, to which reference has been made, the patient, having had a daily discharge of three gills of fat for two years or more, recovered in a few weeks after giving up the occupation of a carpenter and adopting the life of a farmer.

Exclusive of the form just considered, diarrhœa involves different pathological elements, viz., increased peristaltic movements, increased transudation or flux, increased secretion from the mucous follicles, and perhaps, increased flow of bile. The predominance of these elements, generally gives to the discharges the diversities which are observed in different cases. If the diarrhœa be purely functional, of course there is no inflammation of the mucous membrane. It is customary to express the morbid condition of the membrane by the term *irritation*. Practically, however, it must be confessed, it is not always easy to determine whether diarrhœa be purely functional or dependent on subacute inflammation. But, with reference to the treatment, to determine this point is not of great importance. It is not improbable that, of the cases considered as functional, in a certain proportion there is a slight grade of inflammation, such as exists in coryza or a mild bronchitis. In making the diagnosis, acute inflammation is to be excluded by the absence of diagnostic symptoms, viz., pain, tenderness, febrile movement, anorexia. So, also, lesions of the mucous membrane are to be excluded. In cases of chronic diarrhœa this is not always easy. Lesions are to be suspected if the diarrhœa follow an attack of dysentery or enteritis; if it persist in spite of judicious management; if blood be sometimes present in the dejections, and if tubercles exist in the lungs. In the latter case, tuberculosis of the intestine is to be suspected; and, on the other hand, persistent or frequently recurring diarrhœa, conjoined with cough, be the latter never so slight, should excite suspicion of pulmonary tuberculosis.

Transient diarrhœa, due to arrested or defective intestinal digestion, is of frequent occurrence. With the diarrhœa which follows over-indulgence at the table, or the ingestion of certain articles of food, every one is practically familiar. This is the *diarrhœa crapulosa* of the old writers. It may proceed from excesses in quantity, or from particular kinds of food, the indigestibility of the latter, perhaps, showing an idiosyncrasy of the person affected; thus, ices, salads, shell-fish, etc., in some persons always,

and occasionally in all, give rise to transient diarrhœa. The undigested aliment, passing into the large intestine, having undergone chemical changes which the processes of digestion in health prevent, produces irritation, and acts like a cathartic remedy. Frequently the diarrhœa is preceded and accompanied by griping pains, and it may be, under these circumstances, an element of another functional affection, viz., colic. These attacks of diarrhœa cease spontaneously, as a rule, after the expulsion of the undigested matter, and they are rarely considered of sufficient importance to require medical advice.

An arrest of intestinal digestion may take place from causes other than errors of diet, and give rise to diarrhœa. A strong mental emotion may have this effect. I was present at an operation for hernia, when the surgeon, from the mental anxiety incident to his sense of responsibility, was obliged to relinquish the scalpel, and precipitately retire to evacuate the bowels. A gentleman in business receiving, suddenly, unexpected information which led him to know that he was a bankrupt, was immediately seized with diarrhœa. In like manner diarrhœa may arise from an arrest of digestion from an exposure to cold or over-exertion. In these cases the mechanism is the same as when the diarrhœa depends on dietetic errors, the undigested aliment in the large intestine acting like a cathartic.

Diarrhœa, not transient, but continuing more or less, perhaps becoming chronic or recurring at short intervals, also proceeds, in a large proportion of cases, from indigestion. Habitual or frequent indigestion, especially intestinal indigestion, leads to diarrhœa in the same way as when it is transient, viz., the undigested aliment undergoes chemical changes and causes either irritation or sub-acute inflammation of the large intestine. The dejections, as in transient diarrhœa, may be feculent, bilious, mucous, lienteric, or, more rarely, serous. The diarrhœa in these cases is, in fact, an element or symptom of dyspepsia, but not infrequently, the disorder of digestion being confined mainly to the small intestine, dyspeptic ailments, aside from the diarrhœa, are not marked. The frequent or habitual passage of undigested aliment into the large intestine leads to a persisting state of irritation in the latter, or perhaps, in some cases, to a low grade of inflammation. The indigestion thus giving rise to diarrhœa may be produced and kept up by various causes independent of excess or errors of diet; in fact, the causes are those of dyspepsia, mental anxiety often playing an important part in the causation.

It has been customary to attribute diarrhœa, in certain cases, to an excess or a vitiated quality of bile. This causation is inferred when the dejections are notably bilious. This view is not improbable, although not based on positive knowledge. The bile may not be reabsorbed from the alimentary canal, as in health, and hence accumulates in excess, without a morbid increase in the secretion; it may be secreted in undue quantity, or it may have a morbidly irritating property.

Diarrhœa is most apt to occur during the summer season. This may be, in part, explained by the larger proportion of fruit and vegetables in the ingesta during this season, and by the effect of heat in weakening digestion. It may also in part be due to a more abundant secretion, or to a lessened absorption, of bile. It is a much more frequent affection in tropical than in cold or temperate climates. It is apt to occur in travelling, especially in the summer season. Its occurrence is generally attributed to the water drank, but a more rational explanation is to refer it to indigestion caused by dietetic errors, over-exertion, and disturbance of the regular habits of life. Children are far more subject to diarrhœa than adults, especially during dentition, and, in children, the dejections

are often manifestly lienteric, showing its dependence on indigestion. It is the most prominent element of the affection known as *cholera infantum*, or, popularly, in this country, as *summer complaint*. Among soldiers, especially in campaigns during the summer season, or in warm climates, diarrhœa is extremely common, attributable to irregular habits as regards diet, conjoined with the exposure and fatigue incident to active service. Diarrhœa occurs in persons exhausted from the want of food or other deprivations, and in females enfeebled and anæmic from protracted lactation, due in these cases to intestinal indigestion. The same explanation, probably, applies to the diarrhœa which occurs at a late period in cases of pulmonary tuberculosis, and other chronic affections, when not dependent on intestinal lesions. Under these circumstances it has been called *colliquative diarrhœa*.

The accumulation of urea in the blood, as a consequence of renal disease, occasions diarrhœa. The diarrhœa and vomiting which occur under these circumstances, appear to be for the purpose of eliminating, vicariously, urea, and are, therefore, conservative. They occur when the kidneys are removed in inferior animals, and, as shown by the experiments of Bernard and Barriswill, the liquid transudation into the alimentary canal contains either urea or the carbonate of ammonia. The dejections in uræmic diarrhœa are serous or watery.

Another pathological condition, occasionally giving rise to diarrhœa, is congestion of the portal vessels when the circulation in this portion of the vascular system is obstructed by hepatic disease. It thus is a symptom, in some cases, of cirrhosis of the liver, and sometimes appears to limit the dropsical effusion into the peritoneal sac, which belongs to the history of that disease. The diarrhœa, under these circumstances, is serous, transudation taking place from the pressure of the blood within the congested veins.

Crapulous diarrhœa, or transient diarrhœa due to indigestion, in general calls for little or no treatment. If the contents of the large intestine be not spontaneously expelled, an evacuant remedy may be given. A saline purgative is best adapted to this end. The propriety of this measure is to be determined by ascertaining the quantity and character of the dejections which have occurred. If these have been abundant and feculent, a cathartic is not required. If, after the bowels have been freely evacuated, diarrhœa, pain, or uneasiness continue, the irritation may be quieted by a mild anodyne, for example, a drachm or two of the camphorated tincture of opium, for an adult, in chalk mixture, a grain of opium, a sixth or a quarter of a grain of a salt of morphia in mint water, or five grains of Dover's powder combined with two or three grains of aromatic powder. The remedy chosen is to be repeated after six or eight hours, if required. The diet for a day or two should be simple and somewhat restricted. Subsequently a laxative may be required if the bowels do not act spontaneously. The treatment of cases of diarrhœa tending to continuance, or frequently recurring and dependent on indigestion, embraces, in the first place, remedies to relieve the irritation of the large intestine. Opium in some form may be used for this purpose, but only temporarily, because its continued use tends to impair still more digestion. A mild purgative may often be premised with advantage, for frequent and loose dejections are not incompatible with retention of hardened feces, in fact, with constipation. The carbonate or subnitrate of bismuth is an excellent remedy to relieve intestinal irritation. It is often effective, and is not open to the objections of opium. It should be given in doses of from a

scruple to half a drachm to adult patients. If not alone effective, a small quantity of a salt of morphia may be added to it. Of a variety of remedies tried in cases of chronic diarrhœa among soldiers returning from the campaigns in Virginia in the summers of 1862 and 1863, bismuth, in my hands, proved the most effective, and this, I believe, was the result of the experience of others. Opiates are sometimes most effective, and least objectionable, when given *per enema*. Pepsin or the rennet-wine is sometimes useful temporarily as a means of artificial digestion, given as already recommended in cases of dyspepsia.

This part of the treatment, however, is merely palliative. The curative treatment embraces regulation of diet and measures to render digestion complete. The diet, in quantity and quality, should be adapted to the digestive powers. Chickens, eggs, and tender meats plainly cooked, are most likely to be digested, but in some cases a milk and farinaceous diet is found to be preferable. Experience in individual cases is to be the guide. Crude vegetables are to be interdicted, but ripe fruits, in moderation, may frequently be taken without inconvenience and with advantage. A moderate quantity of food, taken at short intervals, is generally advisable, rather than a full meal once or twice daily. In short, the treatment, as regards diet, is essentially that of dyspepsia. This statement will apply alike to hygienic measures relating to exercise, clothing, and mental recreation. A sea-voyage, a visit or removal from the city to the country, or the change of a warm, variable, humid, relaxing climate for an atmosphere cool, uniform, dry, and bracing, will be likely to prove highly beneficial, if not curative, in cases which resist dietetic and medicinal treatment. The efficacy of these measures is strikingly illustrated in cases of the so-called summer-complaint of children.

The remedies, other than those merely palliative, which are useful in the cases of diarrhœa under consideration, belong among the tonics and astringents; the latter may be both palliative and curative. Of the various vegetable astringents, krameria, hæmatoxylon, kino, catechu, and rubus villosus are eligible articles. The tannic acid, if well borne by the stomach, is sometimes efficient. As purely tonic remedies, quinia or the non-officinal preparations of Calisaya bark, of late in vogue, and other bitter infusions, are often useful. Preparations of iron are especially useful when the patient is anæmic, as in cases of diarrhœa occurring in females during lactation. As a purely tonic remedy, the tincture of the chloride of iron is one of the best of the chalybeates. The persulphate or pernitrate of iron is sometimes highly efficacious as an astringent, as well as a tonic remedy. Of mineral tonics and astringents, the acetate of lead, nitrate of silver, and the sulphate of copper have been found useful. The carbonate or the subnitrate of bismuth is of great value in chronic diarrhœa, not only as a palliative but a curative remedy, given in large doses, namely, from a scruple to a drachm, three or four times daily, sometimes in combination with small doses of a salt of morphia, as recommended above, in connection with palliative measures of treatment. The mineral acids are efficacious in some cases. The preparation known as Hope's mixture has been much in use. This mixture is composed of four drops of nitric acid and from forty to sixty drops of laudanum in four ounces of camphor water, a tablespoonful to be taken every two, three, or four hours. In rebellious cases of chronic diarrhœa, the numerous remedies which have been named are to be given in succession, and in various combinations. The curative and palliative remedies are to be combined to meet the indications in individual cases.

Diarrhœa dependent on uræmia, and on cirrhosis of the liver, does not admit of curative treatment, and, being conservative, is only to be kept within certain limits by palliative remedies.

ENTERORRHAGIA.

Hemorrhage into the intestinal canal is properly called Enterorrhagia. The term *melæna* has been used to denote dark-colored or black dejections consisting of blood which has passed from the stomach into the intestinal canal. Partial digestion of the blood, or the action upon it of the gastric and intestinal secretions, renders it tarry or pitch-like in appearance, and generally very offensive to the smell. Dejections of this character are apt to follow gastrorrhagia. The term melæna has been also applied to cases of gastrorrhagia in which the blood vomited presents a similar appearance. Moreover, the term has been loosely applied to denote dark-colored or black evacuations, not consisting of blood. The term is one of those which it is desirable should become obsolete. Cases in which blood evacuated from the bowels comes from the stomach, or from any of the abdominal viscera other than the intestinal canal, are not cases of enterorrhagia. Nor are cases of hemorrhoidal or other hemorrhages occurring near the anus, properly embraced under this head. The source of the hemorrhage must be the mucous membrane between the stomach and rectum. The tarry or pitch-like appearance of blood in the stools is evidence of its gastric source. But this appearance is not positive proof that the matter evacuated is blood. It is probably blood if the stools have been preceded by the vomiting of blood, but, in some cases of gastrorrhagia, vomiting does not take place, all the blood passing into the intestinal canal. In doubtful cases, dilution in water of some of the matter evacuated, renders the appearance of blood more evident, or recourse may be had to the microscope. When the source of hemorrhage is the rectum, the blood is fresh in appearance, and is passed alone, in greater or less abundance, either after a fecal evacuation, or with straining efforts to procure a stool. Examination with the eye or touch, will show the existence generally of hæmorrhoids, but, in some cases, other local affections, such as ulcers, carcinoma, a polypus, or invagination.

In cases of enterorrhagia, the hemorrhage takes place in different situations along the tract of the small and large intestine. The blood is less changed in appearance the nearer the rectum its source, and the more quickly it is evacuated. If the hemorrhage be at the upper part of the intestinal tube, and the blood pass slowly along the tube, it becomes dark or blackish, its appearance approximating to that of the melænic stools in cases of gastrorrhagia, and there may be a smilar difficulty in determining whether the appearance be due to the presence of blood. The quantity of blood passed in different cases of enterorrhagia varies. It is frequently large, amounting, in some cases, to several pints and even quarts. Evacuations may consist wholly of blood, or the blood is mixed with fecal matter. The blood may be entirely liquid, or the evacuations contain clots in more or less abundance.

Intestinal, like gastric hemorrhage, has rarely any claim to be regarded as an individual affection. Like gastric hemorrhage, it is incidental to a variety of morbid conditions. It is an important occasional event in typhoid fever, and will be referred to in treating of that disease. It enters into the characteristic dejections of acute dysentery. It is an effect of ulceration of the bowels in chronic dysentery. It occurs in cases of carcinoma of the bowels. It is a rare occurrence in tuberculous ulceration of the

small or large intestine. In may be a symptom in simple enteritis. It belongs to the natural history of scorbutus, purpura hemorrhagica, and yellow fever. Like gastric hemorrhage, it may be vicarious of menstruation. It is not an uncommon effect of the portal congestion occasioned by cirrhosis of the liver. It occurs, however, when not connected with these or any other discoverable morbid conditions. This was exemplified in a case, under my observation, of an unmarried female aged about 40, who was attacked, when apparently in perfect health, with griping pains in the abdomen, followed by loose evacuations containing blood in large quantity. These evacuations recurred for several days. There was no affection of the rectum, the menses were not suppressed, and the hemorrhage could not be traced to any of the affections of which it is usually a symptom. The enterorrhagia ceased after several days, and the patient recovered her usual health. This patient had several recurrences of the hemorrhage, in the intervals apparently being in perfect health. I have met with a few additional examples of enterorrhagia not connected with any of the several causative conditions which exist in the larger proportion of cases. While, therefore, the chances are that some of these conditions exist, the occurrence of hemorrhage is not proof of the existence of any of them. The discharge of blood in the cases just referred to is generally preceded and accompanied by abdominal pains, probably in part due to the congestion which it is to be presumed precedes the hemorrhage, but partly referable to the presence of the blood within the intestinal canal. Other symptoms are attributable to the loss of blood, and are marked in proportion to the amount of hemorrhage, such as debility, pallor, feebleness of the pulse, perspiration, sense of faintness, etc. The loss of blood may be sufficiently great and rapid to occasion sudden death, but this is rare. The continuance of repetitions of the hemorrhage may lead to a degree of exhaustion and anæmia from which recovery is difficult, and a fatal result may take place by slow asthenia. In general, however, if the hemorrhage be not connected with affections or morbid conditions which involve danger, the prognosis is favorable. In cases of enterorrhagia, as in cases of gastrorrhagia, the amount of hemorrhage is not always represented by the quantity of blood contained in the evacuations. The general symptoms denoting loss of blood are to be taken into account. Hemorrhage sufficient to occasion fatal syncope may take place and no blood be discharged by stool. In such a case, the diagnosis of enterorrhagia is impracticable.

The treatment of the different affections or morbid conditions with which intestinal hemorrhage is usually connected need not be here repeated. It will suffice to refer to measures having reference to the hemorrhage. These are essentially the same as in cases of gastric hemorrhage. Rest in the recumbent position and quietude of mind are important. The peristaltic movements are to be quieted by opium. Cold applications to the abdomen should be made if the arrest of the hemorrhage be urgently indicated. The most effective mode of applying cold is by means of a bladder or an India-rubber bag containing pounded ice. In cases in which this indication is less urgent, dry cupping, sinapisms, and warm stimulating pediluvia will suffice without the application of cold. Food and drinks should be taken cold. The diet should be restricted and bland. Purging is of doubtful propriety. The mineral acids are generally thought to be useful in cases of intestinal, as well as in gastric hemorrhage. The sulphuric acid lemonade has the advantage of being a grateful beverage. The various hemostatic remedies given in cases of gastrorrhagia, viz., gallic acid, acetate of lead, ergot, the astringent preparations of iron, etc., are to be resorted to in proportion to the importance of arresting the hemorrhage.

CHAPTER VII.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINES.—(CONTINUED.)

Constipation. Intestinal Colic. Enteralgia. Lead Colic.

CONTINUING to consider the functional affections of the alimentary canal, this chapter will be devoted to constipation, intestinal colic, enteralgia, and the so-called colic from lead.

CONSTIPATION.

The terms *constipation* and *costiveness* are commonly used as synonyms, denoting insufficiency of evacuations from the bowels. The latter term is sometimes used to denote a less degree of insufficiency than the former, the number of dejections being normal, but the quantity deficient, and the act of defecation labored. The term *obstipation* has been already defined to denote a greater amount of difficulty than constipation, that is, obstruction of the bowels, either as a functional disorder or dependent on various lesions which have been considered in a preceding chapter. Constipation exists as a functional disorder, and it is incidental to various affections. As a functional disorder it is extremely frequent, and, although not a serious affection, it claims attention on account of the inconvenience which it occasions, its importance as leading to other ailments, and the difficulty of its removal unless it be correctly understood and managed.

The affection is seated in the large intestine. The anatomical arrangements of this portion of the alimentary canal show it to be intended to serve as a temporary depot for fecal matter, thus providing against the need of frequent acts of defecation. The contents of the alimentary canal are propelled more slowly along the large than in the small intestine, *first*, because the circumference of the former is larger in proportion to its muscular power; *second*, in the ascending colon the contents are propelled for a considerable space in opposition to gravitation, and, also, for a smaller space, at the sigmoid flexure; and, *third*, the liquid portion of the contents is absorbed in their passage through the small intestine. Experience shows that one free evacuation from the bowels daily is the rule in health. But this rule is not without exceptions. Some persons have, habitually, two or three evacuations daily, and, on the other hand, some have an evacuation regularly every second or third day, without any of the inconveniences of constipation; in fact, persons of the latter habit are apt to experience discomfort if, temporarily, evacuations take place daily. In determining, then, the existence of this affection, the habit in health is, of course, to be taken into account. In some cases, the act of defecation is delayed for one, two, or three days after the period when it should have taken place, but the evacuation, when it does occur, is ample. In other cases, the act occurs daily, but it is incomplete, and in these cases the act is usually labored and painful, the feces being dry, compact, and

hard. The affection may be occasional and transient, or it may be habitual.

Constipation gives rise to various local morbid effects, such as a feeling of pressure or weight in the perinæum, a sense of abdominal distension or uneasiness, flatulency, diarrhœa, and colic pains. Hæmorrhoids are often attributable to this affection. It gives rise, also, to pain in the head, dulness of the mind, flushing of the face, palpitation, and general malaise. If the act of defecation require violent straining efforts, these occasion, sometimes, hemorrhage into the brain, and hernial protrusions. The contractility of the muscular tunic of the large intestine may be permanently impaired by long-continued distension, so that the affection is necessarily permanent.

Occasional constipation is not generally considered of sufficient importance to require medical advice; persons resort, of their own accord, to a purgative or an enema. It is when the affection has become habitual or chronic, that cases come under the cognizance of the physician. And, in order to understand the pathological character of the affection in these cases, and its causation, certain points pertaining to the function of defecation in health are to be borne in mind. In its normal condition, the rectum is, for the most part, empty, as shown by the researches of O'Beirne.[1] This portion of the large intestine is endowed with a peculiar sensibility which, in health, gives notice of the presence of feces, and occasions the desire to defecate. The ability to perform the act involves a certain contractile power in the large intestine, and also in the abdominal and other muscles which co-operate in the performance of the act. In habitual constipation, the contractile power of the intestine is impaired by distension. The muscular tunic is more or less paralyzed from the accumulation of the intestinal contents, in the same way as the bladder becomes paralyzed from over-distension. The accumulation giving rise to the distension may be owing to the large quantity of excrement, but it is generally a result of habitual neglect of the calls of nature. The desire to defecate is resisted, or, the mind being pre-occupied, the call is unheeded, and the act is postponed, until, at length, the sensibility no longer gives notice of fecal accumulation; hence, the accumulation goes on, the rectum and other portions of the large intestine become distended, and paralysis follows. This is the manner in which constipation, as a chronic affection, is produced in a large majority of cases. The hurried performance of the act of defecation, the evacuation being, in consequence, incomplete, has measurably the same result as the neglect of the calls of nature. Instead of receiving adequate attention as important to health, it is considered an annoyance to be escaped from as quickly as possible. The uncomfortable provisions for defecation, especially in the country, contribute to constipation by rendering it disagreeable to devote to the act more time than is absolutely necessary.

Various circumstances may contribute to this affection. The abdominal muscles play an important part in the act of defecation. These muscles become weakened by obesity, and, in females, as a result of pregnancy. The muscular tunic of the intestine, and the auxiliary voluntary muscles concerned in defecation, lose more or less of their contractile power, in common with the whole muscular system, in anæmia, and other enfeebling conditions. Deficiency of bile and the intestinal secretions may enter into the causation in some cases, but probably the importance of this source of constipation has been over-estimated; constipation is not always present

[1] New Views of Defecation, etc. By James O'Beirne. Am. ed., 1834.

when no bile enters the alimentary canal in certain cases of jaundice. The ingestion of purely nutritious food, leaving but little excrementitious residue, contributes to constipation. Sedentary habits are supposed to favor the affection, but it is probable that other causes are generally more operative, and especially inattention to the calls of nature. On the other hand, active exercise induces constipation by rendering assimilation more active, the liquid contents of the small intestine being more entirely absorbed. Loss of fluids by abundant perspiration or by diuresis is another cause. The change of habits, with, generally, an increased assimilation, incident to a sea-voyage, as is well known, induces, in most cases, constipation.

Occasional constipation, if slight, is relieved by a laxative pill repeated, if necessary, or by a small quantity of Epsom or Rochelle salts dissolved in a tumbler of simple or carbonated water, and taken upon an empty stomach. The Congress or Kissingen water may be taken in lieu of the salts just named. But a preferable method, which will generally suffice, is to excite the action of the large intestine by a simple enema of cold water. By means of Davidson's syringe, the patient may resort to this measure without any difficulty. If the constipation be more than slight, a few grains of blue mass or a purgative pill may be taken at bedtime, and followed, if necessary, by a saline draught or an enema in the morning. Persons are apt to resort, without consulting physicians, to purgatives, under an impression that they are always harmless, and generally useful aside from the relief of constipation. Hence, it is common to take active purgatives for slight constipation, and, often, when nothing is required. If the constipation give rise to little or no inconvenience, it is better to wait for spontaneous relief, and a little delay will often show that medicinal interference was unnecessary.

The management of habitual constipation often requires much care and perseverance on the part of the physician and patient. The object is to secure regularity and sufficiency in the evacuations. The means which may be employed are various. They may be arranged into dietetical, medicinal, and mechanical. The dietetical means consist in using freely articles which leave, after digestion, a bulky residuum, viz., cabbage, lettuce, and the various vegetables known in this country as greens; or articles having a laxative property, such as molasses, prunes, figs, etc.; or articles with indigestible constituents which stimulate or irritate the alimentary canal, viz., bran bread, corn meal, groats, or cracked wheat. A diet consisting, in part, of the foregoing articles, will sometimes succeed in obviating habitual constipation. But, with regard to the choice of this class of means, the following practical rule is to be adopted: they are not to be preferred if they disorder digestion or occasion more disturbance than medicines. More harm sometimes results from overloading the digestive organs with articles of diet difficult of digestion, or subjecting the canal to the irritation of unbolted flour, than the continuance of constipation would occasion. A tumbler of simple water, or of carbonated water, taken in the morning before breakfast, is sometimes efficacious.

The medicinal means are laxative remedies. With regard to these, a general rule is, the remedy chosen should be mild, and the quantity as small as will suffice for the object. Purgation is to be avoided. Some patients fall into the custom of allowing the constipation to continue for several days, and then resorting to a free purgative. The constipation is, of course, relieved for the time, but the constipated habit becomes more and more fixed by this course. Another general rule may be stated: If more than one *small* dose of laxative be required, the remedy is to be

given in small doses repeated twice or thrice daily, rather than given in a single dose. In this way the object is effected with a less amount of medicinal impression, and there is less risk of purgation.

As regards the particular remedy, aloes is especially suited to the desired object. It may generally with advantage be combined in a pill with a tonic, either the sulphate of quinia or a preparation of iron, and a small quantity of hyoscyamus or belladonna may be added. A very small proportion of aloes, often a small fraction of a grain in each pill, will suffice. The old preparation known as the elixir proprietatis (tincture of aloes and myrrh) is well suited to this object, a drachm given at bedtime, and repeated, if necessary, once or twice during the day. This preparation loses, with age, its disagreeable bitterness, and is not generally repulsive given with a little water and an abundance of sugar. A small piece of rhubarb taken repeatedly during the day, effects sometimes the object satisfactorily, and this remedy to many persons is not disagreeable. I have known a few drops of the tincture of colchicum, repeated shortly after each meal, to answer admirably. There are various modes of rendering the daily use of a laxative remedy not unpleasant to the taste. Prunes stewed in an infusion of senna answer well, and are not unpalatable. The confection of senna and medicated figs are also suited to persons who take a pill or potion with repugnance. Trousseau claimed for his favorite medicine, belladonna, that it acts as an efficient laxative in cases of habitual constipation. It has failed to have this action in my experience, and I have frequently made trial of it. Here, as in other instances, experience in individual cases is to be the guide. In the majority of cases in which medicinal means are relied upon, some form of the so-called dinner-pills, or, as they have been aptly termed, "peristaltic persuaders," will be found most convenient and satisfactory; and, for the fastidious, they may be silvered or sugar-coated. The white mustard-seed was formerly a popular remedy much in vogue, but this is objectionable on account of a liability to accumulate and become impacted within the intestine. Laxative remedies are not to be continued for a longer period than is required to secure an habitual action of the bowels. A minute dose of strychnia or nux vomica, added to a laxative, is thought by many to render the operation of the latter more successful.

The mechanical means consist in the use of enemas and suppositories. The regular use of an enema of cold water, at the same hour daily, is a simple, and sometimes an effective measure. This measure, however, is better suited to occasional than to habitual constipation. Habitually resorted to, it is apt to fail after a time; the rectum becoming accustomed, as it were, to the stimulus of distension, it ceases to excite the peristaltic movements. In some cases a suppository of soap answers the purpose of provoking a regular and sufficient evacuation. The cocoa-nut butter may be used for this purpose. Common molasses candy answers equally well, an oval mass of the size of a pigeon's egg being introduced within the rectum. This, however, is only a temporary expedient, ceasing usually to be effective after a time.

The most important part of the management in cases of habitual constipation is not embraced in the foregoing measures. It is the adoption of a rule to solicit an evacuation at the same hour daily. The importance of this rule is to be enforced, but, of course, its success will depend on the perseverance of the patient. The time of the day most convenient for the act of defecation is to be selected, and, in general, the most favorable time is in the morning after breakfast. At the time fixed upon, the patient should devote a reasonable period to the function of defecation, but

without persisting in violent fruitless efforts. This should be considered in the light of a duty, not to be omitted a single day except from necessity. It may be long before the desired object is accomplished, but, sooner or later, with the aid of some of the means which have been indicated, the desire will be felt at the appointed hour, and the ability to defecate at that time will be acquired in the great majority of cases. It is impossible to secure regularity and sufficiency of the evacuations without perseverance in this part of the management. The management also includes a rule never to neglect or postpone the call to defecate, when it occurs either after or before the time for the habitual performance of the act of defecation. The importance of waiting for a certain period after the contents of the rectum have been expelled is to be enforced. Often the expulsion of the contents of the rectum is immediately followed by the passage from the colon into the rectum of fecal matter which, remaining, blunts the sensibility of the bowel and renders it accustomed to distension. The objects in the management are to be understood and kept in view, viz., 1st, To preserve or restore the normal animal sensibility of the rectum, by which the presence of fecal matter is felt; and, 2d, To prevent paralysis from distension, and to regain the muscular power which has been lost from this cause.

If this plan were early inculcated and carried out in health, habitual constipation would be as rare as it is now frequent. The prevention is not less sure than simple. The function may be brought fully under the control of habit. This fact should be generally understood, more especially in the training of girls, most of whom become affected with habitual constipation, and suffer from it all their lives. Unfortunately the existence of the function of defecation is too often ignored from notions of false delicacy, and the affection becomes established because parents and teachers are either themselves ignorant of this simple method of prevention, or consider the subject as belonging exclusively to the physician.

INTESTINAL COLIC.

The term colic, in its etymology, relates to the colon, but it is often applied to paroxysmal, spasmodic pain in other parts. Thus, the phrase hepatic colic is used to denote the pain caused by the passage of gall-stones, and nephritic colic the pain caused by the passage of renal calculi along the ureter. A painful affection of the uterus is sometimes called uterine colic. In the present nomenclature of diseases, there is no suffix or prefix which, joined to the name of a part, expresses a painful spasmodic affection of that part. The affection of the alimentary canal known as colic may not be seated exclusively in the colon. It is probable that the small, as well as the large, intestine is affected in certain cases of intestinal colic. As applied to the intestine, colic denotes pain occurring in paroxysms or in marked exacerbations, the pain of a character supposed to indicate spasm, that is, twisting, constricting, or griping. Colic pains are symptomatic of different inflammatory affections, viz., dysentery, enteritis, peritonitis, and of the various lesions which give rise to intestinal obstruction. They enter, also, into the functional affection known as cholera. As constituting an individual malady, colic, of course, is independent of inflammation or structural lesions, and is disconnected from any other functional affection.

An attack of colic is characterized by paroxysms or exacerbations of pain, varying much in severity in different cases, the pain being usually in the region of the umbilicus. The pain is frequently extremely severe;

the patient bends the body forward with the thighs flexed, writhes, and tries a variety of positions, groaning or crying aloud from the intensity of suffering. The severe pain continues for a few moments, and then either ceases completely or abates, to return again with the same severity after an interval usually of brief duration. If left to continue without measures for relief, an attack may embrace a few paroxysms only, or it may last for several hours. An attack lasting for a short time, and ending in one or more free evacuations from the bowels, is so common as to be familiar to every one.

The abdomen, in attacks of colic, is frequently retracted, but, in some cases, it is more or less tympanitic. Generally, there is absence of tenderness, and firm pressure with the hands, or lying upon the belly, affords relief; but in some cases there is more or less soreness and tenderness on pressure, especially over the site of the cæcum. During the paroxysms of pain, the abdominal muscles are sometimes spasmodically affected, especially the rectus muscle, the sections of which are felt as hard bunches. Usually there is constipation. Nausea is sometimes present and occasionally vomiting. The pulse is but little, or not at all, accelerated. The skin is cool, and, during the severity of pain, frequently bathed in perspiration.

In a case presenting the characters just described, it is important to determine, as soon as practicable, the existence simply of a functional affection, that is, to differentiate colic from affections in which pains like those of colic occur. The diagnosis is to be made by excluding these affections. Dysentery is readily excluded by the absence of the dejections characteristic of that disease. Enteritis is excluded by the absence of the symptoms denoting inflammation. The pain, in these two affections, is rarely as violent as in most cases of colic; but in cases of acute peritonitis, the exacerbations of pain may equal in violence those of a severe attack of colic, and the error of confounding these two affections has been committed in not a few instances. The exclusion of peritonitis is to be based on the absence of notable tenderness over the abdomen, of rigidity of the abdominal walls, of frequency of the pulse, and of other general symptoms denoting a graver affection than colic. Invagination, internal hernia, and other obstructive lesions cannot always be at once excluded. As a rule, the paroxysmal pain occurring in connection with these lesions at the outset, and, indeed, all along, is less violent than in colic, and, after a time, the existence of something more than colic is shown by persisting pain, tenderness, vomiting of the so-called stercoraceous matter, sometimes tenesmus, frequency of the pulse, prostration, etc. The absence of these symptoms, after a time, warrants the exclusion of obstructive lesions. The possibility that some obstructive lesion may exist is not to be lost sight of in cases which at first have the appearance of simple colic. The possibility of inguinal or femoral hernia is also to be borne in mind, and a careful examination with reference to this point is not to be omitted. The resemblance of labor-pains to those of colic is to be recollected. Pregnancy is sometimes concealed, and it has happened that the physician, supposing his patient to be suffering from colic, has been taken by surprise at the cry of a newly-born infant under the bedclothes.

The several varieties of colic which writers have generally recognized do not require separate consideration. Some of these varieties rest on an insufficient basis. The colic has been called crapulous when it proceeds from indigestion. Every one is familiar with the attacks which are apt to follow over-indulgence at the table, ending frequently in crapulous diarrhœa. A colic is called flatulent when accompanied with tympanites,

or the expulsion of gas with relief. This variety is most apt to occur in infancy. The term bilious colic has been used when the affection is supposed to depend on hepatic derangement. This dependence is merely conjectural, and there is no more reason for continuing to append the word bilious to this affection, than to various others in which the coexistence of disorder of the liver is equally hypothetical. Colic has been called stercoraceous when attributable to the retention of feces; but the latter is perhaps oftener an effect than a cause of colic. In another variety called verminous, the colic is supposed to depend on the presence of worms, but it may fairly be doubted whether colic ever proceeds from this source. The variety called saturnine or lead colic is properly a distinct affection, and will be considered as such.

The morbid condition in colic is supposed to be spasm. Its seat is, therefore, the muscular tunic of the small or large intestine. That this is the pathological character of the affection, is shown by the kind of pain, the constipation, together with the local symptoms, and the therapeutical measures which are found to be successful. It is not improbable, as supposed by Abercrombie, that, in certain cases, the spasm may be preceded by paralysis of a section of the intestinal tube, and consequent obstruction to the passage of its contents. Like other spasmodic affections, it may be produced by causes which act either directly upon the part affected, or indirectly through its nervous communications. The late Prof. Charles Hooker, of Yale College, in an interesting paper on intestinal auscultation, published in 1849, states that, during an attack of colic, borborygmal sounds indicating the peristaltic movements of the intestinal tube are suspended, and that the termination of the attack is preceded by a return of these sounds for some time before the complete relief of pain.

Attacks of colic are frequently, if not generally, attributable to the local action of the ingesta. They may arise from indigestion caused either by excess in quantity, or the indigestible quality of food. They not infrequently follow exposure to cold or fatiguing exertions, but these causes probably act by occasioning indigestion. Certain articles of diet, for example shell-fish, in some persons, give rise to attacks of colic in consequence of an idiosyncrasy which is inexplicable. The muscular tunic of the intestine is especially susceptible to spasm in infancy, and colic occurs much oftener in early than in middle and advanced life. A susceptibility to intestinal spasm belongs to some persons, constituting a predisposition to this affection. In the practice of every physician there are those who are subject to attacks of colic more or less frequently. This predisposition may continue for a certain number of years, and then disappear. Persons with this predisposition often have an uncomfortable sensation of weight, coldness, or numbness in the abdomen, with general languor and irritability, preceding the development of colic, and by means of these premonitions they are able to predict an impending attack.

Although attended with great, and, if not efficiently treated, often protracted suffering, colic is not a dangerous affection. It may be doubted if, alone, it ever prove fatal. It is one of those violent functional affections from which recovery takes place rapidly. It has no tendency to eventuate in inflammation or any other disease, but, in proportion to its duration, it is followed by fatigue or weakness, and more or less abdominal soreness may remain for some time.

The object of treatment is the relief of spasm as indicated by the cessation of pain. Measures are to be directed to this object without reference to the cause of attack, or the existence of constipation. If, as is gene-

rally the case, an attack have been induced by the presence of irritating ingesta, measures directed to the spasm should take precedence of evacuants; and if, as is frequently the case, the bowels were constipated at the time of the attack, the removal of this condition is a secondary object. So long as spasm continues, there is a resistance to the action of cathartics, and to defer measures for the relief of pain until the bowels have been evacuated, is to prolong needlessly the sufferings of the patient.

In mild attacks, warmth to the abdomen and extremities, a little spirit not largely diluted with hot water, some aromatic stimulant, such as anise, ginger, cloves, mint, etc., or a few drops of chloroform, will suffice to procure relief. Twenty drops of chloroform, repeated, if necessary, at short intervals, will sometimes afford prompt relief in severe cases. If not, opium in some form is to be given to the extent of procuring freedom from pain. Administration *per enema* is to be preferred. A drachm of laudanum with the same quantity of the tincture of assafœtida, in a small quantity of mucilage or starch, may be injected, with injunctions to the patient to resist the desire to expel it, and, usually, in a short time, this desire passes off. If complete relief do not follow in the space of an hour, the enema may be repeated. If the suffering be extremely intense, double this quantity of laudanum, in the case of an adult, may be given in the first or second enema. If necessary, the enema may be repeated a second or third time. A similar plan is to be pursued as regards the doses and repetitions, if the opiate be given by the mouth. Hot fomentations or dry heat should be applied to the abdomen. Speedy success may be counted upon by pursuing this plan of treatment.

The subsequent treatment is to be determined by circumstances relating to the abdomen. If no inconvenience be felt, measures to effect a movement of the bowels need not be employed for twenty-four or even forty-eight hours. Not infrequently, if the physician be not in haste to give a cathartic, a sufficient evacuation occurs spontaneously. If measures to effect a movement be required, a large simple enema may suffice; if not, a mild saline purgative may be given in divided doses, or castor-oil if this remedy be not offensive to the patient. The diet for a day or two should be simple and restricted.

The certainty with which colic yields to an efficient opiate treatment renders it one of the affections which exemplify very palpably the resources of medicine. Some patients, however, suffer considerably from the after-effects of the opium given, and this in a measure compromises the mutual satisfaction of the physician and patient in the success of the treatment. Persons who are unfortunately affected unpleasantly by most forms of opium are sometimes able to take certain preparations with less inconvenience than others. The experience of the patient on this point should be consulted.

ENTERALGIA.

The term enteralgia denotes a neuralgic affection referable to the intestines. It has, to the latter, the same relation as gastralgia to the stomach. Gastralgia and enteralgia may be associated. Enteralgia and colic are not infrequently confounded, nor is it always easy to distinguish, clinically, the one from the other. Enteralgia is characterized by pain within the abdomen, with intermissions or remissions, the pain having more or less intensity, but lacking the twisting or griping character of the pain in colic. It may be so severe as to lead to contortions and oral expressions of suffering. In females, enteralgia is an element of attacks of tympanites

due to the secretion of gas, and is apt to be associated with hysterical phenomena.

The diagnosis involves the exclusion of the various affections from which colic is to be discriminated and the exclusion of the latter affection. Rheumatism of the abdominal walls is also to be excluded. According to Valleix, lumbo-abdominal neuralgia bears a close resemblance, as regards the seat, etc., of pain, to enteralgia, but it is to be discriminated by the existence of tenderness in front at the umbilical or hypogastric region, and also at the points in the lumbar and lateral portions of the body, whereas, in enteralgia, tenderness on pressure is generally wanting.

The treatment involves the same principles as the treatment of gastralgia and other neuralgic affections.

LEAD COLIC.

The affection now commonly known as saturnine or lead colic has been described by writers, at different times and places, under a variety of names. Painter's colic, plumber's colic, colic of Poitou or colica pictonum, Devonshire colic, colic of Madrid, vegetable colic, rachialgia, dry bellyache, and other names which might be added, all relate to the same affection, which is one of the varied forms under which lead-poisoning is manifested. For the evidences of the correctness of this statement, the reader is referred to treatises entering into the consideration of the affection more largely than is consistent with the scope of this work. The affection differs from ordinary colic as regards not only its causation and clinical history, but its pathological character; it is not a spasmodic, but a neuralgic affection, that is, a variety of enteralgia.

The affection is developed usually in a gradual manner, and is preceded by prodromic phenomena which are the general effects of lead-poisoning, viz., pallor due to anæmia, and frequently an icterode hue of the skin, a peculiar fetor of the breath and a metallic taste in the mouth, loss of appetite, constipation, pain in the limbs, more or less emaciation, and muscular debility. Pain in the abdomen is at first comparatively slight and progressively increases, becoming, at length, the chief ailment. The pain is oftenest referred to the region of the umbilicus, but sometimes to the epigastrium or hypogastrium, and it may be limited to other situations, or it may extend over the whole abdomen, but it is usually confined within a small space. The pain frequently shoots into the back, the genital organs, and in other directions. The pain is sometimes dull or aching, and, at other times, acute and lancinating. It varies, in different cases, within wide limits, as regards intensity. In a mild form it merely occasions annoyance, like the pain in certain cases of gastralgia, but in a severe form the suffering is extreme, causing the patient to assume a variety of unnatural and fantastic positions, and to utter loud groans or cries, as in severe cases of gastralgia and ordinary colic. The abdomen may be more or less meteorized or tympanitic, but it is oftener depressed and resisting to pressure. The resistance to pressure is caused by tonic contraction of the abdominal muscles, and this, in some cases, is a marked feature of the affection. Pressure on the abdomen, if made gradually and over a considerable space, is generally well borne, and often affords relief; patients are apt to lie upon the belly, with a folded pillow, or some other substance, and sometimes the closed hand, placed under them over the seat of pain. Pressure, however, with the ends of the fingers or percussion of the abdomen may not be well borne. The bowels are constipated, the exceptions to this rule being infrequent, and the dejections frequently

consist of small hard lumps, or scybala. More or less nausea occurs in a majority of cases, and not infrequently vomiting. Hiccough and eructations of gas are not uncommon. The appetite is lost. The urine is scanty and micturition is sometimes difficult and painful. Circumscribed projections or tumors, changing their situation, and due, evidently, to an accumulation of gas in a portion of the intestinal tube, have been observed. The pain may be exclusively in paroxysms, the patient, in the intermissions, being entirely free from it, but much oftener more or less constant pain is experienced with exacerbations. The paroxysms or exacerbations vary much in different cases in duration, as well as severity. They may last for a few moments only, or continue for several hours. The intermissions or remissions also vary in duration from a few moments to hours and even days.

In conjunction with the foregoing local symptoms, there is no febrile movement unless there be some accidental complication. The pulse is abnormally slow, and frequently irregular. It is generally fuller and harder than in health. The skin is cool. The mind is anxious and depressed. The strength fails in proportion to the severity of the pain and the duration of the affection. The affection may be complicated with other manifestations of lead-poisoning, viz., paralysis affecting certain of the voluntary muscles, and especially the extensors of the forearm, amaurosis, neuralgia in different situations, occasionally epileptiform convulsions, delirium, and coma. The latter have been embraced by Tanquerel and other writers under the name lead encephalopathy.

The affection has no definite duration, in this respect resembling neuralgic affections in general. When left to itself, it may end in a few days, or after the lapse of weeks, and, if the patient continue to be exposed to the cause, it may persist for an indefinite period. In itself, it involves little or no danger to life, nor is there ground to believe that it leads to any serious abdominal disease. But other effects of lead poisoning, which may complicate or follow this affection, especially the effects embraced under the name lead encephalopathy, are liable to end fatally. The affection frequently pursues an irregular course, varying in severity much at different periods; and relapses, after all the symptoms have ceased for days or weeks, without any fresh introduction of lead, are not uncommon.

The introduction of lead into the system in sufficient quantity to give rise to its morbid effects, may take place through the lungs, the stomach, the mucous membrane in other parts, and the skin. Certain occupations involve the inhalation of lead. Persons employed in the manufacture of lead-paints are most exposed, and, of those who suffer from lead-poisoning, the largest proportion are of this occupation. Next to this class, painters are most exposed. More or less exposure, by inhalation, belongs to a great number of occupations, such as paper-staining, grinding of colors, glazing cards, manufacturing earthen pottery, plumbing, shot-making, etc. Lead-poisoning has repeatedly occurred from sleeping in newly-painted rooms. Lead may be introduced through the stomach in various articles of food and drink. The colic of Poitou was due to wine, and that of Devonshire to cider adulterated with lead in order to give it sweetness. This kind of adulteration has been practised since the occurrence of the affection in the places just named, and it is perhaps still sometimes resorted to. Liquid and solid articles of diet, especially if they contain a free acid, become impregnated with lead by being in leaden vessels or earthen vessels glazed with lead. Some years ago a large number of persons within a limited district in Ohio were affected with a disease which, for some time, was regarded as a novel epidemic, and received the name of dry

cholera. It was found to have the diagnostic characters of lead colic, and was traced to the common use of a cheap kind of earthen-ware made in that vicinity, into the glazing of which lead entered.[1] Prof. Fenner, in the *Southern Medical Reports*, vol. i., describes an epidemic colic which he observed in New Orleans, and which he traced to lead contained in soda-water; and my colleague, Prof. Doremus, some years ago, demonstrated the presence of lead in considerable quantity in the soda-water drawn from fountains in this city (New York). Water distributed in lead pipes is not infrequently the vehicle of its introduction into the system.[2] Lead sometimes enters into the substances used to color confectionery, condiments, and other articles, in sufficient quantity to give rise to poisonous effects. Articles inclosed in lead foil may become contaminated. Authentic instances of poisoning by the use of tobacco thus inclosed have been reported; and in France inclosing tobacco in lead is prohibited by law. The habit of chewing shot and pieces of the lining of tea boxes has been known to give rise to various manifestations of lead-poisoning lasting for four years before the cause of disease was discovered.[3] During the spring of 1866 two hundred and thirteen cases of lead-poisoning occurred in the Walkill Valley, Orange Co., New York. After considerable research it was ascertained that lead was contained in the flour and meal used in that part of the country. The source of the lead was ascertained to be the stones used for grinding the meal and flour. The stones were old, constantly needing repair, large cavities frequently occurring, which instead of being filled up with cement were filled with common lead. The attrition of the grinding detached minute particles of lead, and the lead thus becoming mixed with the flour and meal was transformed into the carbonate by the processes of fermentation and baking.[4] These are only a few of the diverse modes in which lead finds its way into the alimentary canal. Its use as a remedy has given rise to colic and other morbid effects. It may be introduced through the skin, although doubtless with difficulty. Prof. Lewis Rogers, of Louisville, has informed me that he has known the characteristic paralysis called wrist drop, fairly attributable to the long-continued application, to the hands and face, of a cosmetic containing lead; and my colleague, Prof. Sayre, has reported a case in which this manifestation of lead poisoning followed the use of the article known as "bloom of youth." I have known a case in which phenomena denoting lead poisoning were attributable to the use, for a long period, of a dressing for the hair containing the acetate of lead. Finally, instances of lead-poisoning by means of collyria and vaginal injections have been reported.

The diagnosis of lead colic, in most cases, is not difficult. If the occupation of the patient involve obvious exposure to lead, a suspicion of the nature of the affection is, of course, at once aroused; but this, and other manifestations of lead-poisoning not infrequently occur in persons who are not aware of any such exposure, and it may require no small pains to discover the mode in which the poisoning has taken place, after the character of the affection has been ascertained. The diagnostic characters of lead colic as compared with those of ordinary colic, offer points of difference which enable the physician to discriminate it from the latter. The gradual development, the occurrence of remissions much more frequently than

intermissions, the persistency of the affection, the concurrence of pain in the back, limbs, and sometimes in the chest, the occurrence of nausea and vomiting, the obstinacy of the constipation, and frequently dysuria, characterize this affection when contrasted with ordinary colic. Coexisting paralysis in some cases, especially if limited to the extensor muscles of the forearm, strengthens the diagnosis. Enteritis and peritonitis are excluded by the absence of symptoms denoting inflammation. Enteralgia, exclusive of its occurrence in connection with hysteria, is so rare, excepting when produced by lead, that its existence is strong presumptive evidence of this causation. A valuable sign was indicated by Tanquerel in his treatise on Lead Diseases, published in Paris in 1838, and its diagnostic importance enforced by Dr. Henry Brinton in a paper read before the London Medical and Chirurgical Society in 1840. This sign consists in a blue or slate discoloration of the gums at their junction with the teeth. The blue line on the gums may be apparent on the upper or lower jaw or on both. It is wanting in sections where teeth have been lost. It is most marked in proportion as the teeth are incrusted with tartar, and in persons who neglect cleanliness in this situation. The discoloration is attributed to the formation of the sulphuret of lead, sulphuretted hydrogen being evolved from the decomposition of particles of food remaining between the teeth and beneath the margin of the gums. The presence of the lead to combine with the sulphuretted hydrogen may be readily accounted for, if it be introduced, as is usual, into the system through the mouth either with the inspired air or in food or drink; but there is ground for the belief that sufficient lead may be eliminated in this situation to account for the sign. The sign is not present in all cases. Its absence, therefore, is not proof that lead colic does not exist. Clinical observation, however, shows that the sign is present in a large majority of cases. It is found frequently to precede the development of colic and other affections dependent on lead-poisoning. It is not a transient sign, but is apt to persist, not only during the continuance of the affection, but for some time afterward. In a diagnostic point of view it is highly important, and the gums should be examined with reference to it whenever lead-poisoning is suspected. A chemical analysis of the urine may show the presence of lead in this fluid. In the case reported by Prof. Sayre, just referred to, my colleague, Prof. Doremus, obtained from the urine sufficient lead in the metallic form for clinical illustration.

The treatment of lead colic embraces palliative and curative measures. The pain is to be palliated by anodynes given by the mouth or rectum, conjoined with soothing applications to the abdomen, as in cases of ordinary colic. Chloroform given by the mouth and applied over the abdomen is stated by Aran to act promptly and efficiently in relieving the pain. If this prove ineffectual, opium in some form will be required, the doses and their repetitions to be graduated by the intensity and persistence of the pain. Relief is afforded by free purgation, and, for this end, saline, or such other cathartics as the stomach will best support, may be given, and their operation aided by large purgative enemata. The obstinacy of the constipation often renders it difficult to procure free evacuations from the bowels, and active cathartics may be required. Tanquerel advocated the efficacy of croton oil, a drop to be given twice daily. He regarded active purgation as curative, and this is the view generally held. Drastic purgatives entered largely into the complicated treatment instituted by monks in the hospital *La Charité*, in Paris, in the beginning of the 17th century, and, with various modifications, continued ever since in that hospital. The employment of cathartics may be useful in removing lead contained in the

contents of the alimentary canal. The warm bath is useful as a palliative, soothing measure.

Several remedies have been supposed to have a curative efficacy in this affection. Alumen is one of these. Its efficacy was advocated especially by Brachet, in a prize essay on the subject of lead colic, who stated that he treated 150 patients with this remedy more successfully than by opium and purgatives. From one to two drachms of alumen were administered during the day in a ptisana to which 40 or 50 drops of laudanum were added, a mild aperient given on the third day, and the alumen continued for two or three days after the symptoms of the affection have disappeared. Other observers, Briquet, Tanquerel, and Grisolle, have not met with a similar success from the alum treatment. Sulphuric acid has been advocated especially by Gendrin, on the basis of remarkable success in a large number of cases. A drachm of dilute sulphuric acid in a quart of sweetened water forms a pleasant drink resembling lemonade, and this may be taken in the twenty-four hours. Tanquerel denied the efficacy of this remedy, giving, as the basis of his denial, the results of its trial in 53 cases. The success of Gendrin's method, however, is attested by Dr. Bennet, who was a pupil and house physician of Gendrin for three years.[1] The prophylactic efficacy of the sulphuric acid lemonade appears to have been satisfactorily proven in the lead works at Birmingham, England.[2] Strychnia or nux vomica has been recommended as a curative remedy by Huss, Neligan, and, in this country, by Dr. Bulkley, and the late Dr. Swett.[3]

The remedy regarded in this country now, and of late years, as possessing most curative power, is the iodide of potassium. The use of this remedy as a curative agent, in the treatment of lead diseases, and also those due to the presence of mercury in the system, dates from the publication, in the *Annales de Chimie et de Physique*, in 1849, of a paper by Melsens.[4] Assuming, as is generally believed, and as facts appear to prove, that the local manifestations of lead-poisoning are due to the presence of an insoluble compound of lead in the tissues of the affected parts, Melsens claims for the iodide of potassium the power of effecting the liberation of the lead and its elimination from the system. The iodine is supposed to combine with the lead in the tissues, forming a soluble compound which passes out of the body in the urine. Chemical examination of the intestines, the paralyzed voluntary muscles, and other organs, in cases of lead-poisoning, has shown the presence of lead in larger quantity than is to be accounted for on the supposition that it may exist in the body in health. The examination of the urine in cases of lead-poisoning under treatment with the iodide of potassium, has shown the presence of lead, its absence in this liquid having been ascertained prior to the treatment.[5] Finally, clinical observation appears to afford proof of the curative efficacy of this treatment. Further evidence of the latter, consisting in the results of the treatment in a large number of recorded cases, is a desideratum. With reference to the therapeutics of this, as of other affections, knowledge of its natural history as regards termination when left to its own course, is important. Tanquerel, in his valuable treatise, gave the results

[3] Stillé's Therapeutics, vol. ii. p. 247.

[4] For a translation of this paper by William Budd, M. D., the reader is referred to the British and Foreign Medico-Chirurgical Review, January, 1853.

[5] For facts verifying this statement, see a report of the results of the treatment with the iodide of potassium in 23 cases, in the New York Hospital, by H. S. Swift, M. D., New York Medical Times, February, 1854.

in 31 cases in which no treatment was pursued for 12 days after admission into hospital, the affection having existed for one or more days before admission. Of 8 of these cases in which the colic was violent, in 3 a spontaneous cure took place within the 12 days, viz., on the 3d, 8th, and 11th day. Of 13 cases in which the colic was of moderate severity, in 5 a spontaneous cure took place on the 4th, 7th, 8th, 9th, 11th day, and in 1 on the 13th day. Of 10 cases in which the colic was light, in 6 a spontaneous cure took place within the 12 days.

In the treatment of lead-poisoning by the iodide of potassium, Melsens enjoins to commence with moderate doses, and to increase the doses gradually. He supposes that disturbance may arise from dissolving the lead out of the tissues rapidly. Five grains may be given three times daily at first, and the quantity increased to a drachm *per diem*, if the remedy occasion no inconvenience.

The utility of the warm bath as a palliative measure has been already referred to. It may perhaps be useful in promoting the elimination of lead through the skin. It is useful by removing from the skin lead which comes into contact with and adheres to the surface in persons engaged in certain occupations. The sulphurated or sulphurous bath may be employed for the latter object. This is made by adding four ounces of the sulphuret of potassium to thirty gallons of water in a wooden bathing-vessel. The use of this bath renders the presence of lead on the skin apparent by the production of a dark discoloration which is readily removed by a brush. The blackness is marked in various parts of the body in painters and workmen employed in the manufacture of the preparations of lead used as paints, especially if they have neglected cleanliness; but it may be due to the presence of lead eliminated from the body and remaining adherent to the surface. The bath renders the lead which may be in contact with the skin inert, and it is useful as affording evidence that the surface of the body is entirely free from lead, whether derived from without or eliminated.

Prevention of the continued introduction of lead into the system is an essential part of the management. The occupation is to be suspended if it involve exposure; and if the affection be renewed, or there be other manifestations of poisoning, on resuming the occupation, it should be exchanged for some other. If the source of the poisoning be not apparent, it is to be sought for until found. This poison is one which gives no notice of its entrance into the body, and no manifestations of its presence until a certain amount of accumulation has taken place. The affection under consideration is but one, although the most frequent, of the forms of disease to which it gives rise. There is reason to think that obscure and indefinite ailments are not infrequently produced by it in cases in which suspicion of the cause is not awakened, and the liability to these, as well as the more marked effects, from the use of water conducted in lead-pipes and various other sources, some of which have been enumerated, is one of the important subjects pertaining to public health.

The protection of those necessarily exposed to an atmosphere more or less charged with lead, or to contact with it, is also an important subject. Much may be done to prevent its introduction by attention to ventilation, clothing, baths, washing the mouth, and the occasional use of purgatives. Special means of protection, such as the application of moist sponges to the mouth and nostrils, or the use of masks, under certain circumstances, may be important.

After recovery from the colic, an anæmic condition, with general debility, will often claim appropriate medicinal and hygienic measures of treatment.

COLIC FROM COPPER.

Writers have described a form of colic supposed to be produced by the introduction and accumulation of copper in the system, and the term *metallic colic* has been used to embrace, not only the colic due to lead, but abdominal pains, with other symptoms, attributed to copper, mercury, and arsenic. The diagnostic features of so-called copper colic, as contrasted with lead colic, have been considered to be as follows: Limitation of pain to the abdomen, increase of pain by pressure, enlargement more frequently than retraction of the abdomen, diarrhœa with greenish stools, and infrequency of nausea or vomiting. An extended and careful examination of numerous establishments in which the workmen were exposed to emanations from and contact with copper in various modes, conducted by Chevallier and Boys de Loury, in Paris, led to the conclusion that such an affection as colic from copper does not exist.[1] This conclusion, however, is by no means inconsistent with the fact that copper within the system exerts a deleterious effect. Arsenic and preparations of mercury, taken in quantities sufficient to produce the phenomena of a local acrid or irritant poison, give rise to pains which may resemble those of colic. Accumulating within the system, these minerals occasion certain toxical effects, but they do not, under these circumstances, lead to abdominal symptoms which may with propriety be considered as an individual affection under the name of colic.

CHAPTER VIII.

Sporadic Cholera—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Cholera Infantum. Epidemic Cholera—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Prevention—Treatment.

OF the functional affections of the stomach and intestines, enumerated in a preceding chapter, two remain to be considered, viz., sporadic and epidemic cholera. Cholera infantum, belonging among the diseases of children, does not come within the scope of this work. I shall, however, notice it briefly, referring the reader, for a fuller consideration of it, to works devoted to the diseases of children.

Sporadic Cholera.

The affection called cholera, in its ordinary form, is commonly known as *cholera morbus*. Aside from the incongruity of associating these two words, the one Latin and the other of Greek derivation, there is no good reason for appending the word morbus, which expresses no more than is implied in the name of any affection, viz., the existence of disease. The etymology of the term cholera is somewhat doubtful, but it is supposed to signify a flow of bile. The term is of ancient date, and was introduced when various liquids were embraced under the name bile. Not only is

[1] *Vide* Nysten's Dictionaire de Médecine, etc., 1858. Also, Valleix, *op. cit.*, tom. v.

the term sanctioned by long usage, but it would be difficult, with our present knowledge, to substitute a better name for the affection under consideration. The term sporadic serves to distinguish this from another affection, known as cholera, which prevails as an epidemic. To distinguish it from the latter, which emanated from India, it is sometimes called by French writers, *European*, and by British writers, *English cholera.* Writers on this side of the Atlantic might, with equal propriety, call it American cholera, since it is sufficiently common, as an indigenous affection, in America. It is called by German writers *cholera nostras.*

Clinical History.—An attack of sporadic cholera is often abrupt, but, in some cases, is preceded, for a period usually brief, rarely longer than a few hours, by a sense of weight or uneasiness referred to the epigastrium, or extending more or less over the abdomen, with nausea, occasional colic pains, etc. The attack occurs much oftener in the night than in the daytime. It is ushered in by vomiting, which is speedily followed by purging. Vomiting and purging, occurring in quick succession, and recurring either simultaneously or in close alternation, constitute the prominent, distinctive, symptomatic features of this affection.

The evacuations from the stomach and bowels are generally abundant, and, at first, consist of the alimentary and fecal contents. Afterwards, liquid is vomited, sometimes in large quantity, often having the appearance and taste of bile, sometimes acid, and sometimes so acrid as to occasion a scalding sensation in the throat. In like manner, the dejections become liquid, and occasion frequently a burning sensation at the anus. The acts of vomiting and purging occur suddenly with but little premonition. They are often violent, the contents of the stomach and bowels being ejected with force. The acts of purging are preceded and accompanied by colic pains, often extremely severe, which are temporarily relieved by a free evacuation. Severe pains, like those of spasm or cramp, often attend the acts of vomiting. In the intervals between the acts of vomiting, the patient usually suffers from dryness of the mouth and fauces with urgent thirst. The abdomen may be at first voluminous, but after repeated acts of vomiting and purging, it becomes contracted. Tenderness over the abdomen is either wanting or slight. Spasm of the abdominal muscles sometimes occurs, causing hard bunches or knots as in some cases of colic. Hiccough is an occasional symptom.

With the foregoing local symptoms are associated anxiety, restlessness, and a sense of exhaustion proportionate to the violence and duration of the attack. The pulse is more or less accelerated, small, and feeble. The skin is cool or even cold, and is frequently bathed in clammy sweat. The voice is feeble, sometimes altered in quality, and occasionally there is aphonia. In some severe cases cramps occur in the feet, the calves of the legs, and in other situations. These add greatly to the suffering of the patient.

The affection runs a rapid course. After continuing for several hours, the acts of purging and vomiting become less severe and occur at longer intervals, the pains, etc., progressively diminish, until, at length, all the symptoms disappear, leaving an amount of fatigue proportionate to the violence and duration of the attack. The patient usually rapidly recovers. It is remarkable that an affection involving so much disorder should leave the affected organs in a condition to resume so speedily the exercise of their functions. This is the rule as regards the progress and termination of the affection, even if its course be not arrested by remedial interference. Exceptionally, the vomiting and purging continue, the evacuations from

the bowels occur involuntarily, the pulse becomes more and more feeble, coldness of the surface is more and more marked, contraction of the features takes place; in short, the patient falls into a state of collapse, and dies within a few hours from the date of the attack. This unfavorable course is extremely rare. I cannot recall an example that has fallen under my observation, exclusive of cases occurring in infancy.

Pathological Character.—Sporadic cholera appears to combine morbid conditions belonging to other functional affections of the alimentary canal. In a certain proportion of the cases considered as cases of cholera, the symptoms are attributable simply to indigestion. Vomiting and purging denote, in these cases, the coincidence of acute dyspepsia and crapulous diarrhœa. These cases are usually comparatively mild, and the vomiting and purging cease as soon as the offending contents of the stomach and bowels are expelled. In other cases something more than indigestion is involved in the pathology. The evacuation of liquid, often in great abundance, shows hyper-secretion or morbid transudation into the stomach and intestines. The affection then combines gastrorrhæa and enterorrhœa. In some cases the secretion of bile would seem to be increased, but it is difficult to estimate, from the color and the bitter taste of the vomited liquid, the relative proportion of bile. It had been common to suppose that in this, as in various other affections, disorder of the liver is in some way involved. There is no solid foundation for such a supposition; it rests on conjecture alone. It is only in a certain proportion of cases that the bile appears to be secreted in morbid quantity. The limit of our present knowledge of the pathological character of the affection is reached when the different morbid conditions into which it is resolvable are enumerated. These morbid conditions, or elements of the affection, are indigestion, irritation, spasm of the muscular coat of the stomach and intestines, enteralgia, morbid gastric and intestinal transudation, and, perhaps, in some cases, hyper-secretion of bile. By German authors the affection is considered as a variety of gastro-intestinal catarrh.

Causation.—Sporadic cholera is not peculiar to any country, but is of more frequent occurrence in warm than cold climates. In cold and temperate latitudes it occurs very rarely except during the summer and autumnal months. An elevated temperature is thus involved in its causation, either by contributing to the development of causes, or by rendering the system more prone to be affected by them. The affection occurs oftener in childhood, youth, and middle age than in advanced life, and oftener in males than females. Frequently an attack seems to be attributable to the ingestion of particular articles of food or drink. Uncooked vegetables, fruits, ices, etc., are often supposed to stand in a causative relation to it. An attack may follow the arrest of digestion from various causes. In some cases, as already stated, the affection is apparently due to indigestion alone. It is probable that, exclusive of these cases, the affection involves a special cause, the nature and source of which are unknown.

Diagnosis.—The diagnostic features of an attack of sporadic cholera are so strongly marked that little need be said under this head. Yet there is some liability to errors of diagnosis. I have known a case of acute peritonitis, accompanied by vomiting and purging, to be considered as a case of cholera, the nature of the disease not being discovered until the autopsy was made. It is extremely rare for vomiting and purging to

have sufficient prominence, early in peritonitis, to lead to this error. The diagnostic marks of peritonitis, however, which will be considered in the next chapter, should always be sought after in cases of apparent cholera. The chief liability to error in diagnosis relates to cases of poisoning from the ingestion of acrid or corrosive substances. It is important to discriminate these cases from cholera, with a view to antidotal treatment, prognosis, and medico-legal considerations. The following are the differential points: The acrid or corrosive poisons occasion vomiting which continues for some time before diarrhœa occurs, whereas in cholera the purging is simultaneous with or follows quickly the vomiting. Moreover, the vomiting in cases of poisoning is out of proportion to the diarrhœa. The symptoms in cases of poisoning denote a condition of greater gravity; the pulse is more frequent and smaller, the expression is more haggard, etc., than in the majority of the cases of cholera. Redness or charring of the mouth and throat distinguishes certain cases of poisoning. There is marked tenderness over the stomach in cases of poisoning, and more constant, excruciating pain in this situation, in the intervals between the acts of vomiting—in short, the symptoms of gastritis are present. The matter vomited is more apt to be bloody. Finally, in cases of poisoning the symptoms are developed directly after a meal, or the ingestion of something containing the poison.

Prognosis.—As already stated under the head of the clinical history, this affection in the vast majority of cases intrinsically tends to recovery. A fatal termination is a rare exception to the rule; yet the fact that the termination is sometimes fatal is to be borne in mind and should enforce prompt and effective measures of treatment. Occurring in persons already affected with some important disease, the prognosis is, of course, not so favorable as when healthy subjects are attacked.

Treatment.—In the treatment of sporadic cholera, the first point is to ascertain whether the matters vomited have contained ingesta in more or less abundance. If not, and there be reason to suppose that the stomach contains undigested aliment, a mild emetic may be given. Almost invariably, however, the contents of the stomach are expelled with the first acts of vomiting, and, as an emetic is indicated for no other object, it is very rarely called for. In my own experience I have not prescribed an emetic in this affection for the last twenty or more years. The next object is to arrest the vomiting and purging, together with the pain, etc., by the employment of some form of opiate in doses sufficient to effect this object. In the vast majority of cases, this object may be speedily effected. The form of opiate should be chosen with reference to promptness of action and its being retained. Laudanum, the black drop, and an aqueous solution of opium are well suited to the management of this affection, but Majendie's solution, or a salt of morphia placed dry upon the tongue, is, in general, the best form. A full dose—half a grain of a salt of morphia, or an equivalent dose of any other preparation, to an adult—should be given directly after an act of vomiting. The first dose will perhaps be immediately rejected; if so, a second should be at once given. If a second and third dose be instantly or quickly rejected, the administration by the mouth should be abandoned, and from one to two drachms of laudanum, or an equivalent dose of some other preparation, may be given in a little thin starch or mucilage *per enema*. The enema should be given directly after an evacuation, and the patient should be instructed to resist as long as possible the inclination to expel it. If the first enema be

quickly rejected, a second and a third may be given. If the attempt to administer the opiate by the mouth and rectum fail, the hypodermic injection may be resorted to. In whatever way the remedy be introduced, it is to be repeated after an interval of from half an hour to an hour, until the vomiting and purging are arrested, the effects of each dose being carefully watched, and the intervals being sufficiently long to avoid any risk of inducing narcotism.

An important part of the treatment is withholding from the patient liquids. His intense thirst leads him to drink largely between the acts of vomiting, and this tends to prolong the affection. He should be restricted to a tablespoonful of ice water at short intervals, or, what is better, to small pieces of ice which may be taken frequently and allowed to dissolve in the mouth. Strict compliance with injunctions on the score of drink is essential to the prompt success of the treatment. If there be great prostration, a little spirit and water may be taken, if retained, at short intervals.

In my experience this method of treating sporadic cholera has proved uniformly successful, and complete relief may generally be expected within an hour. No apprehension need be entertained with respect to the sudden cessation of the vomiting and purging; the more quickly the arrest is made, the better, after a free evacuation of the stomach and bowels. Mercury is, to say the least, superfluous. The success of treatment without it is all that could be desired.

Care as regards diet is alone required, in most cases, after the affection is arrested.

I do not deem it necessary to consider other methods of treatment, since the success of the plan just stated is, so far as my experience goes, uniform and immediate. The only objection to the plan is, that some persons are unpleasantly affected by opium, and, after the affection is arrested, the effects of the remedy may be more or less annoying for a time. This objection has not much weight, since the after-effects of opiates, however distressing, occasion far less suffering than the continuance of cholera. But they who frequently experience annoyance after the use of opium, under certain circumstances take it without inconvenience, and I have been led to observe that the after-effects are apt to be slight or wanting when opium is given, in this affection, to patients who usually suffer from these effects.

Cholera Infantum.

The name cholera infantum, or the more popular phrase *summer complaint*, is supposed, by some, to denote an affection peculiar to this country. The morbid phenomena, however, considered by American writers as belonging to this affection are described in European works under other names. Cruveilhier enumerates many of the symptoms as occurring in cases in which gelatiniform softening of the stomach is found after death, a form of softening already referred to, which is probably due to the action of the gastric juice post-mortem.[1] British writers on diseases of children generally describe the symptomatic phenomena under the head of diarrhœa. Weaning brash, watery gripes, and choleric fever of children, are names under which these phenomena have been described by Cheyne, Armstrong, and Copland. By some French writers they have been described as belonging to colo-enteritis, follicular enteritis, choleriform diar-

[1] *Vide* page 403.

rhœa of children, and gastro-intestinal catarrh. German authors consider the affection as incidental to gastro-intestinal catarrh.

As commonly used in this country, the term cholera infantum, or summer complaint, embraces different pathological conditions, in fact, distinct affections, occurring in children under two years of age. These different conditions, however, may be developed at different periods in the same case. In certain cases the symptoms closely resemble those of the sporadic cholera of adults. A child is seized with vomiting and purging, the latter usually occurring first; the acts of vomiting and purging are violent and frequently repeated; after the contents of the stomach and bowels are expelled, the evacuations consist of secreted or transuded liquid in more or less abundance. The attack may cease or be arrested and recovery speedily ensue, as in cases of the sporadic cholera of adults; but this favorable course does not obtain so generally in children as in adults. If the course be unfavorable, the vomiting and purging continue; the child is tormented with thirst, but everything is rejected from the stomach; great prostration ensues; collapse follows, and death takes place in one, two, or three days. The fatal result may be preceded by convulsions and coma. In some cases the violent symptoms of cholera cease, and the attack eventuates in a chronic affection, accompanied by diarrhœa and occasional vomiting.

In other cases, the affection is gastro-intestinal indigestion. These are characterized by diarrhœa, the dejections being lienteric and watery. Vomiting occurs only occasionally, and is an accidental symptom. It may even not occur at all. The diarrhœa is more or less persisting, the discharges being often green in color, an appearance which Golding Bird, and, more recently, Dr. J. Lewis Smith, have shown not to depend on vitiated bile;[1] the appetite is impaired or lost; colic pains are apt to be troublesome; the child progressively wastes, and death may take place from inanition. In another class of cases, the affection is either enteritis or entero-colitis. The dejections in these cases contain gelatinous or stringy mucus, which is not infrequently tinged or streaked with blood. Febrile movement, with remissions, occurs in these cases. There is more or less abdominal tenderness and pain. Vomiting may be prominent as a symptom, or it occurs only occasionally. Progressive emaciation and debility mark the unfavorable progress of this affection. Head symptoms are often developed in its course. The child becomes dull and somnolent, lies with the eyelids partially closed, and frequently rolling the head from side to side. Convulsions and coma may occur before death. After death, an examination reveals the evidences of inflammation of the mucous membrane of the small, and, perhaps, also, of the large intestine, the follicles being especially involved. Enteritis or entero-colitis is liable to become developed in the cases which, at first, appear to be cases of diarrhœa dependent merely on indigestion. In still another class of cases the symptoms and the appearances after death denote the existence and limitation of inflammation to the large intestine.

Under the name cholera infantum, then, are commonly embraced cases of sporadic cholera, diarrhœa from indigestion, enteritis, colo-enteritis, and dysentery. The head symptoms which are apt to be developed in

[1] *Vide* article by Dr. Smith in the American Medical Times, Sept. 20, 1862. Dr. Smith in this article states, as a conclusion drawn from 37 autopsical examinations, that there is no evidence of congestion, torpidity, hyper-activity, or perverted secretory action of the liver in cases of cholera infantum or summer complaint. *Vide*, also, Smith on the Diseases of Children.

unfavorable cases of each of these affections in the young child, were formerly attributed to inflammation of the meninges of the brain. They were supposed to denote a metastasis to the head. The attention of the profession was called to the incorrectness of these pathological views by the writings of Gooch and Marshall Hall. It is not easy to say precisely what the morbid condition is, but it is not inflammation, and it is dependent upon the exhaustion produced by the abdominal affection. It is sometimes distinguished as the hydrencephaloid condition. Softening and injection of the cerebral tissue were found by Dr. Hallowell in cases in which coma and convulsions preceded death, but there was no evidence that these changes were due to inflammation.[1]

The affections embraced under the name cholera infantum are not, as already stated, peculiar to America, but they doubtless prevail to a much greater extent in certain parts of this country than in Europe, owing, probably, in a great measure, to the heat in the summer months being greater here than abroad. The causation has relation to elevation of temperature; the affections prevail almost exclusively during the months of June, July, August, and September. Something more than temperature is concerned in their production, for they are almost limited to cities and large towns, and are more prevalent in the Northern and Middle than in the Southern States. Children of the poorer classes, in insalubrious situations, living in crowded dwellings, are more liable to be affected, but the children of those in easy circumstances, and of the wealthy, by no means escape. The irritation of dentition and the change of diet after weaning, doubtless, render the system more liable to be affected. Infants brought up by hand are especially subject to these affections. The diet of the child, after weaning, has much to do, if not with the causation of these affections, at least with the ability of the system to resist and overcome them. Restriction to insufficient articles of nourishment, such as arrowroot and gelatin, is one source of innutrition in infancy, but there is reason to believe that infant mortality in cities is attributable, in no small measure, to the use of diluted, sophisticated, and artificial milk. The importance of undiluted milk from a pure source to the welfare of children is far from being generally appreciated. The quality of milk is comparatively of little consequence after childhood, because it then usually enters but little into the diet, but, as the chief reliance is upon milk in infancy, its purity is then of the utmost importance.[2]

The general principles which should govern the management of the same affections after the period of early childhood, are applicable to the different forms of disease embraced under the head of cholera infantum, with certain modifications which will be here referred to very briefly. The treatment, in the first place, will have reference to the form of cholera infantum which is presented. In the acute form, resembling the cholera of adults, in which there is a liability to a rapidly fatal termination by exhaustion from loss of fluids, the patient falling into a state of collapse, the indications are to arrest the vomiting and purging, to restore warmth

[1] *Vide* paper in American Journal of Medical Sciences, July, 1847.

[2] It is almost impossible to impress on the public mind certain important facts as a basis of sanitary reforms. The following quotation from the appendix to Pereira on Diet, written by the American Editor, Prof. Charles A. Lee, twenty-five years ago, is as pertinent now as then: "We have inspectors of flour, of leather, of tobacco, of meat, fresh and salted, of fish, and almost every article of merchandise, but for milk, which is the chief source of sustenance to the young, no inspection is provided; and to judge from the apathy hitherto displayed in relation to it, we have no good reason to expect such a salutary regulation."

to the surface by the application of dry heat, mustard-water, and the warm bath, and to sustain the powers of the system by stimulants and nourishment. Exclusive of this form, the affections do not occur with a sudden and violent attack, but, as a rule, are developed gradually and tend to become chronic. They occur when the system is reduced by dentition together with the change of diet incident to weaning. The use of opium cannot be resorted to in any of the affections as efficiently as when they occur after childhood. It is a maxim applicable to all the diseases of infants, that opiates are to be given with great circumspection. Keeping in view these considerations, the treatment will relate, in the first place, to the relief of vomiting and diarrhœa. Measures for the relief of vomiting are a sinapism to the epigastrium, creasote, which, in doses of a sixth or an eighth of a drop in mucilage, repeated after each act of vomiting, sometimes acts like a charm; the subcarbonate of bismuth in doses of from 10 to 30 grains; small doses of calomel with chalk, chloroform, and hydrocyanic acid. With reference to this symptom, a careful regulation of the ingesta is requisite, and milk with lime-water, given in small quantity at a time, will often be retained when other articles of nutriment are rejected.

With reference to the diarrhœa, occasionally a laxative is useful, and a few grains of calomel or blue mass followed by the syrup of rhubarb, are well adapted for this purpose. There are no indications for mercury except as a remedy for vomiting, and an occasional laxative remedy, the convenience of its administration being perhaps its chief recommendation in cases of young children. Opium in some form, with due circumspection, is to be employed. It is most efficient when given by enema, provided it be administered with proper care and retained. If given by the mouth, the Dover's powder is an eligible preparation. If the dejections denote acidity, chalk, in powder or mixture, or lime-water, is indicated. The mineral and vegetable astringents are highly important. Of the mineral astringents, the most efficient are, bismuth, lead, and the persulphate or pernitrate of iron. The nitrate of silver is highly recommended by Rilliet and Trousseau. Of the vegetable astringents, krameria, tannic acid, kino, catechu, hæmatoxylon, geranium, and rubus villosus, are articles from which a selection may be made, or which may be tried in succession.

Attention to diet and regimen is of prime importance. Many children, there is reason to believe, die with these affections from an insufficiency of nutriment. Pure milk is the most appropriate article of food. It may be rendered more nutritious by the addition of boiled flour, powdered biscuit, or other farinaceous preparations. Gelatin and arrowroot, or other amylaceous substances, are inadequately nutritious. The essence of meat and strong broths are often taken with avidity by very young children, and the desire for them should be indulged and encouraged. This remark is also applicable to broiled tender meats taken in a solid form. Within the past few years, the use of raw meat, introduced by a Russian physician, Weisse, has been highly recommended by Trousseau and others, as a form of diet adapted to the affections under consideration, and observation shows that it is frequently taken with relish. My late colleague, Prof. Elliot, advocated strongly this form of diet in these affections. Tender beef is to be preferred, but mutton and chicken are sometimes more acceptable to the patient. The meat is to be finely hashed, and may be given in this way, or it may be made into a kind of *purée* by being reduced to a pulp in a mortar and pressed through a fine sieve, so as to separate the vessels and areolar tissue. If the child mani-

fest an aversion to it as thus prepared, the hashed meat, or pulp, may be rendered palatable by the addition of salt, sugar, or some kind of preserve, or it may be added to a broth made with sago or tapioca.[1] My own experience, as regards the use of raw meat, is too limited to serve as the basis of an opinion, but I have had considerable opportunity of observing the value of cooked solid animal food, and I cannot avoid the suspicion that the latter is generally more acceptable, equally digestible, and not less nutritious. The liability to tænia, as a result of eating uncooked meat, is not to be overlooked. Trousseau states that this occurred twice in a case under his observation. Weisse, who introduced this mode of alimentation, states that the production of tænia has been repeatedly observed in St. Petersburg.[2]

As regards the administration of different kinds of food, the quantity given at a time is to be graduated by the ability of the stomach to retain and digest it; and this is the only rule of limitation. Trousseau states that for some days after commencing the use of raw meat, it may be found undigested in the stools, but, at length, the digestion of it becomes complete. It is of vast importance for the physician not to deem it too trivial to enter into full and minute directions with respect to the details of nourishment. He should bear in mind that children often die from innutrition through the apprehensions and ignorance of nurses and mothers.

In conjunction with diet, alcoholic stimulants are highly useful. A few drops of brandy, or some kind of spirit, may be given, at short intervals, with advantage. The preparation known as Calisaya cordial or elixir is well suited to children, combining a tonic and stimulant in a form agreeable to the taste. The need of a stimulant is shown frequently by the avidity with which children take it in these affections.

Finally, removal from the city, either to a situation on the seaboard or to a salubrious point inland, is the most efficient of all curative means. This measure, if not deferred too long, rarely fails. If other measures be not speedily successful, this, whenever practicable, should be resorted to without delay. If it be not practicable, the child should be in the open air as much as possible, and should be carried daily as far from home as convenient, in order in this way to secure a change of air.

The head symptoms referred to in the brief notice of the clinical history claim sustaining measures—stimulants and nourishment—conjoined with mild revulsives.

In these affections, hope of recovery need not be relinquished under an assemblage of symptoms which may seem to render the prognosis as unfavorable as possible. Patients sometimes recover after lingering for a long time on the verge of the grave. The reason is, the affections, when they prove fatal, do not necessarily involve incurable lesions of structure, but a fatal result is due to protracted irritation, exhaustion, and innutrition.

Epidemic Cholera.

The term epidemic cholera is selected as the one most frequently used and the most convenient to designate a disease which has received a great variety of names, such as Indian, Oriental, and Asiatic cholera, cholera asphyxia, spasmodic cholera, malignant, pestilential cholera, etc. etc. The etymology of the word cholera, it is true, is singularly inappropriate,

[1] *Vide* Trousseau: Clinique Médicale, tome second.
[2] Traité des Entozoaires, par Davaine, Paris, 1860, page 91.

accepting the derivation which signifies a flow of bile; but our present knowledge does not warrant a name expressive of the pathological character of the disease. Moreover, it is to be presumed that the disease is not essentially the same as sporadic cholera; the two are not merely different varieties of one disease, but they are distinct individual affections, having certain prominent symptoms in common, but differing in essential points relating to clinical history, pathological character, causation, and prognosis.

For an account of the prevalence of this remarkable epidemic in different countries at different epochs, the reader is referred to other works.[1] Suffice it to say that the disease appears to be indigenous in India, and to have existed there, both as a sporadic and epidemic affection, for a long period. In other parts of the world it has made brief visitations solely as an epidemic. In 1817 it commenced its march from Bengal, and during the following 15 years it traversed nearly the whole of the known world. It prevailed in different parts of the American Continent for the first time in 1832, and again 1834. It began its march a second time from India in 1847, and again traversed the greater portion of the globe, prevailing in the United States in 1849, '50, '51, and '52. Commencing again its march over the globe in 1864, it reached this country in 1866 and during this and the following year it prevailed in many of the large towns in the different States of the Union. It may be proper to add that my opportunities for observing the disease in 1849 and 1852 were ample. During these years I treated, in hospital and private practice, about 200 cases, recording, at the bedside, the histories in about 90 cases. A few cases came under my observation in 1866 and 1867.

Anatomical Characters.—Epidemic cholera has no constant, appreciable, anatomical characters which appear to be commensurate with the gravity of the disease. The morbid appearances after death do not afford an adequate explanation of the symptomatic phenomena, nor do they elucidate the pathology of the disease.

The mucous membrane of the stomach and intestines present, frequently, more or less alteration in color, due to submucous congestion. The color is a rose or livid red. But in some cases it presents a white, blanched appearance. Ecchymoses are occasionally observed. The mucous surface is covered with a viscid albuminous layer containing disintegrated epithelium. The mucous membrane of the stomach, especially in the large cul-de-sac, is frequently softened. It gives an alkaline, instead of the normal acid, reaction. Microscopical examination shows the membrane of the stomach and intestines to be more or less denuded of epithelium. Of the lesions found, the absence of gastric and intestinal epithelium is most entitled to be considered in the light of an anatomical characteristic of the disease. This lesion is by some considered as occurring prior to the gastro-intestinal transudation and sustaining to the latter a causative relation; by others it is regarded as secondary to the transudation. The isolated glands or follicles are often abnormally large, and, in a certain proportion of cases, also the Peyerian patches. Small vesicles containing a serous-like liquid have been observed in the small intestine, by Horner and others. They are not constant, and hence have no claim to be considered an anatomical characteristic. They resemble sudamina or the miliary eruption on the skin. The contents of the stomach and intestines,

[1] *Vide* The origin and travels of Asiatic Cholera, by John C. Peters, M.D., New York Medical Journal, August, 1871.

existing in greater or less quantity, correspond to the discharges during life. The mesenteric glands and pancreas present nothing abnormal. The liver is sometimes congested; otherwise not altered. The gall-bladder usually contains bile, but sometimes a matter resembling glairy mucus. The spleen is contracted and sometimes softened. The kidneys are more or less congested. The urinary bladder is empty, and contracted to a small size resembling the virgin uterus. The ganglions and nerves of the sympathetic system present nothing abnormal.

The cavities of the heart contain a small or moderate quantity of dark blood, mostly liquid, with some soft black coagula, and sometimes small fibrinous clots. Analysis shows notable deficiency of albumen, fibrin, and all the constituents of the serum, while the coloring matter is augmented. The blood is less readily oxygenated on exposure to the atmosphere, than after death from other diseases. The lungs, in some cases, contain but little blood, and in other cases more or less hypostatic congestion is observed. Œdema, hepatization, and splenization of portions of the pulmonary organs are occasionally observed. The pleura is covered with a viscid substance like glue, and this is true of other serous membranes.

The membranes of the brain, and the brain itself, are more or less congested. There are usually considerable subarachnoid infiltration and effusion into the ventricles. The effusion into the arachnoid cavity in a considerable portion of cases is sanguinolent. This appearance was noted in 15 of 33 autopsies made by Prof. John C. Dalton, in 1849.[1] The spinal cord offers nothing abnormal.

Cadaveric rigidity is marked, and continues for a long period. In some cases, shortly after death, visible twitchings of the muscles occur, and occasionally considerable movements of the limbs. I have, in several instances, been called, under these circumstances, to determine whether life was actually extinct. Extensive movements, in these cases, may be produced by blows upon the muscles. The heat of the body becomes developed, in some cases, a few hours after death in a remarkable manner, so that the temperature is notably greater than before death. The temperature has been known to rise to 104° Fahr. The muscles of the body are notably dry.

There is much variation, in different cases, as regards the morbid appearances just enumerated. Certain of the lesions, viz., enlargement of the intestinal follicles, pulmonary œdema, and hypostatic pneumonia, are very rarely found if the career of the disease have been short; and when life is very quickly destroyed the tissues sometimes show little or no morbid alterations. That the disease does not necessarily involve any important lesions of the solid parts, is shown by the rapidity with which recovery takes place in some cases in which the disease is promptly arrested.

Clinical History.—In the great majority of cases, the development of the disease is preceded by simple diarrhœa, the dejections being more or less numerous and copious, and unattended with pain. The duration of this preliminary diarrhœa varies in different cases from a few hours to several days. With this diarrhœa in some cases occasional vomiting occurs. Aside from these symptoms, nothing denotes the tendency to the disease. The system otherwise is but little, or not at all, disturbed, and it is difficult to persuade the patient, often, that the intestinal disorder is of any

[1] For a full report of the autopsical appearances in these 33 cases, *vide* Report of the City Physician of Boston (Prof. Henry G. Clark), 1849.

special importance. Of 45 cases in which the existence, or otherwise, of premonitory diarrhœa was noted in the histories which I have recorded, it existed in 34 cases and was wanting in 11. Statistics on a larger scale show a much smaller proportion of cases in which the premonitory diarrhœa is wanting. Thus, the report of the General Board of Health of London for 1848–49, contains the statement by Dr. MacLoughlin, one of the sanitary inspectors, that of 3902 cases the premonitory diarrhœa was not wanting in a single case. Of 142 cases treated in hospital, in Paris, by Michel Levy, the premonitory diarrhœa was wanting in only six. Of 274 cholera cases treated in the different Parisian hospitals in 1853, the existence of premonitory diarrhœa was ascertained in 140, in the remainder of the cases it being absent or its existence not ascertained. By some the period during which the premonitory diarrhœa exists is reckoned as a stage of the disease. This is obviously improper, as there is nothing then distinctive of epidemic cholera, and during the prevalence of the epidemic very many have the same kind of diarrhœa without the development of cholera. The simple diarrhœa which prevails extensively during the prevalence of cholera, is called, in France, *cholerine*, a term adopted, to a considerable extent, in other countries. In a practical view, the importance of taking cognizance of the premonitory diarrhœa is very great, as will presently appear.

The development of cholera is generally first denoted by characters relating to the intestinal evacuations. If diarrhœa have existed, the discharges are suddenly increased in quantity, or sudden and copious liquid discharges, without previous diarrhœa, mark the onset of the disease. This constitutes the attack, which, in the majority of cases, occurs during the night. The characteristic stools, which follow the expulsion of the fecal contents of the large intestine, consist of a thin liquid resembling whey or rice-water, generally known as the rice-water or choleraic discharges. The appearance of the stools in different cases varies, but, in general, their positive or negative characters render them highly distinctive of the disease. The liquid may be clear, like water, semi-translucent, milky, muddy-looking like ditch-water, and occasionally resembling gruel. It contains, in more or less abundance, small, white, solid particles, like grains of rice in rice-water or flakes of curd in whey; these are found, on microscopical examination, to be composed of epithelium, a few pus-globules or leucocytes, molecular granules, with an amorphous substance and mucus. It is devoid of bile, and has little or no fecal smell, but emits a nauseous spermatic oder, compared by Bouillaud to that of the alkaline chlorides. It usually contains no feces. The quantity expelled at each act, or in the aggregate, is very variable. A large quantity, enough to nearly fill an ordinary chamber-pot, sometimes escapes at a single dejection, or the quantity with each act may be small. The quantity is not always in proportion to other symptoms denoting gravity. It may exist in large quantity within the intestinal canal, when a small quantity only is discharged. The dejections are not accompanied by pain, but by a sensation of relief. There is no smarting at the anus. The patient is suddenly impelled, by a sense of distension, to evacuate the bowels, and, when the quantity is large, it escapes very rapidly. In some cases the evacuations, after several have occurred, cease; in other cases, after a time the liquid flows away constantly, the patient being unable to prevent it. Occasionally the dejections are slight, and they may even be wanting. In these cases transudation occurs, but the effused liquid is retained within the intestinal canal. Borborygmus and gurgling are more or less marked.

Vomiting usually occurs. In a diagnostic and pathological view it is

less important, as a symptom, than the characteristic diarrhœa. In some cases it is a prominent and persistent symptom, everything taken into the stomach being rejected; in other cases it occurs occasionally, and sometimes it occurs at the onset and ceases. The matter vomited is a watery liquid, frequently consisting chiefly of water which has been drank, but sometimes evidently an effused liquid. The choleraic effused liquid has an alkaline reaction. The vomiting is not preceded nor accompanied by much nausea. The act of vomiting occurs suddenly, and appears to arise simply from distension of the stomach.

These symptoms mark the invasion of the disease. And these symptoms, conjoined with a sense of prostration, more or less feebleness, and, generally, frequency of the pulse, coolness of the skin or perspiration, with, in some cases, cramps of the muscles of the limbs, may constitute the clinical history of the disease. In other words, the disease may either end spontaneously or be arrested, without advancing beyond the stage which may be distinguished as the stage of invasion. The vomiting and purging cease, improvement as regards other symptoms follows, convalescence is at once declared, and recovery is rapid. The duration, in these cases, of the disease is brief—a few hours only. But in a large proportion of cases the disease does not pursue such a favorable course. A group of striking symptoms becomes developed, and the disease passes into what has been called the algid or cyanosed stage, or, more commonly, the stage of collapse. It remains to sketch the clinical history when the disease does not end with the stage of invasion.

Important symptoms pertain to the circulation. The pulse is usually frequent and proportionately feeble, beating 120, 130, or 140 per minute, but in some cases it becomes more and more feeble without acceleration. I have observed it to fall below the normal frequency. When the state of collapse is fully developed, the pulse at the wrist is extinct. Feebleness or absence of the apex-beat of the heart and of the heart-sounds also show greatly diminished power of the central organ of circulation. The blood stagnates in the veins, giving rise to lividity at the roots of the nails, and a dusky hue of the prolabia, face, and surface of the body generally. Hence, the significance of *cholera cyanosis* and *cholera asphyxia* as names of the disease. If venesection be practised, the blood trickles from the aperture, not flowing in a projected or continuous stream. Leech-bites do not bleed as usual. The blood is manifestly thicker than in health.

The respiratory system presents some striking phenomena. The number of respirations is usually increased, but sometimes diminished. Dyspnœa is occasionally complained of, and sometimes exists in a distressing degree. The respiration is frequently suspirious or sighing, and irregular in rhythm. The expired atmosphere, when the collapse is complete, is low in temperature as compared with health (76° or 80° Fahr.), giving to the hand a sensation of coolness. It contains more oxygen and less carbonic acid than in health, showing a notable deficiency of the changes incident to the function of respiration. The voice undergoes a marked change, becoming feeble, raised in pitch, husky, and, not infrequently, extinct, attributable in part to muscular debility, but chiefly to dryness and stiffness of the vocal cords. In the moribund state the tracheal rales which so often precede death from other diseases is wanting.

Very little pain is experienced except from muscular contractions or cramps. As regards the nervous system, the disease is characterized by mental indifference or apathy. The patient has no apprehensions, although prior to the attack there may have been intense dread of the disease. In

some cases there is great restlessness and jactitation, and in other cases the patient lies quietly save when disturbed by evacuations and cramps. The latter give rise to most of the suffering. Cramps are usually, but not invariably, present. They are seated especially in the feet, calves, and abdominal walls, the muscles of the upper extremities, and even the face being somewhat affected. The prominence of this symptom renders the name *spasmodic cholera* significant. The muscular strength, in some cases, is retained in an extraordinary degree. Patients, if not prevented, will sometimes get up and walk about even a few moments before death.

The function of most of the secretory organs is nearly or quite suspended. No bile is contained in the matter vomited nor in the dejections; the urine diminishes and is at length suppressed. Patients do not weep. It is a remarkable fact, however, that in nursing women the lacteal secretion continues. The disease, also, does not interfere with the occurrence of menstruation, but the menstrual discharge is diminished. The skin, in addition to its cyanosed appearance, is cold and often covered with a copious, viscid perspiration; in other cases it is cold and dry. The coldness of the surface is like that of a cadaver. Of this, however, the patient is not conscious; on the contrary, he generally complains of a sense of heat, and often insists on being uncovered. The heat of the body is diminished, as shown by the thermometer in the rectum or vagina, the axilla, in this disease, not giving a fair representation of the internal temperature. The diminution ranges generally from two to four degrees below 98°; but it may fall to 90°, and even considerably lower; it has been known to fall to 73°. The skin is frequently shrivelled, and wrinkled like the arms of washerwomen. Its elasticity is diminished, as shown by its subsiding very slowly after being pinched up. The tongue gives to the touch a sensation of coldness.

Thirst is a prominent symptom; the patient craves constantly cold drinks, and iced-water or ice is taken with great avidity.

The general aspect in the collapsed stage is highly characteristic. The features are contracted, the eyes sunken, the whole body is diminished in bulk, the patient appears to have suddenly grown old, and the countenance is often so much changed that the person is scarcely recognizable by familiar friends.

Of the foregoing symptoms, most are present in all cases in which the disease is not speedily arrested. The differences in different cases relate chiefly to the degree of the severity of the disease. In stating the condition of patients, it is customary to say *before* or *after* collapse, and to express different degrees of the collapsed state by saying *semi-collapsed* or *completely collapsed*. The collapse is complete when the pulse at the wrist is extinct, the surface cold, etc. The collapse may ensue with more or less rapidity—from an hour to six or eight hours. It occurs almost invariably in fatal cases, the mode of dying being, of course, by asthenia; but I have known cases to end fatally without the stage of collapse, the patient becoming comatose and dying by apnœa.

If the patient emerge from the state of collapse, he does not, in general, pass at once into convalescence, but there follows a period of the disease commonly called the *stage of reaction*. In this stage there is more or less febrile movement, the temperature rising more or less above the maximum of health. Diarrhœa not infrequently continues, the dejections becoming green and gelatinous. Dysentery is sometimes a sequel. In other cases constipation, more or less obstinate, follows. Vomiting, in some cases, is a troublesome symptom in this stage, the vomited matter

being either green or yellow. Capillary congestion of the surface, especially of the face, is frequently marked, as in cases of typhus. The secretion of urine shortly returns, and the urine is apt to be albuminous. This stage is not devoid of considerable danger. The patient may be worn out with continued vomiting or diarrhœa; somnolency and coma become developed in a certain proportion of cases, dependent, probably, on uræmia; delirium, of a passive kind, is not uncommon, together with subsultus, sordes, and other symptoms of the typhoid state. Pneumonia is sometimes developed. A fatal termination occurs in a pretty large proportion of the cases in which the stage of reaction takes place; and in the cases which recover, the powers of the system are generally impaired for a long period. Exceptionally, patients emerge from the collapsed state, and pass, either gradually or quickly, into convalescence without febrile movement and other symptoms belonging to the stage of reaction. The rapidity of the recovery in a certain proportion of cases shows that the gastric and intestinal epithelium, if exfoliated, may be quickly reproduced.

Pathological Character.—The first appreciable important event in the clinical history of this disease is transudation into the alimentary canal. The characteristic dejections and the contents of the intestines found after death consist of water in great abundance holding in solution a little albumen, and, according to Mialhe and Becquerel, albuminose, together with several saline constituents, the most abundant being the chloride of sodium, and an abundance of desquamated epithelium. The white solid particles or flakes contained in the dejections consist, in a great measure, of epithelium, and this causes the opacity when it exists. The blood, of course, loses what is transuded into the alimentary canal. From the loss of water the blood becomes dense and viscid. The blood-globules are relatively in excess, owing to the loss of water. The serum of the blood is deficient in the saline elements which have escaped with the transuded water. The salts of potassa and the phosphates, however, remain. The fibrin is not diminished. The albumen is relatively greater in proportion than in health, but actually diminished. The serum of the blood contains more or less urea.

Most of the striking phenomena of the disease are plainly attributable to the blood-lesions resulting from the loss of the constituents found in the choleraic dejections. The blood circulates with difficulty, and the changes incident to respiration take place imperfectly; hence, the feebleness and extinction of the pulse, the cyanosis, loss of temperature, thirst, mental apathy, spasm, unchanged expired air, defective secretion, etc. etc. The retention in the blood of excrementitious principles, doubtless, plays an important part in the production of morbid phenomena. The coma which occurs in some cases may be due to uræmia. Cholesteræmia probably exists, since the function of the liver is suspended.

The transudation, however, which is first in the catenation of appreciable events, involves an underlying and, at present, inappreciable pathological condition. The latter must be understood in order to know fully the pathological character of the disease. It is probable that the primary, essential change is in the blood; that, in consequence of this change, the water of the blood, holding in solution saline constituents, transudes into the alimentary canal. According to Robin, the essential pathological change is an isomeric modification of the coagulable constituents of the blood-plasma, in consequence of which they part with the water entering into their composition, and lose the power of appropriating water; hence,

the transudation by exosmosis, and defective absorption or endosmosis. It is fair to infer that the primary essential change is not in the solid structures of the alimentary canal, from the rapidity with which recovery takes place when the disease is promptly arrested. This fact shows that the primary essential blood-change is transient and admits of speedy readjustment, provided the immediate effect of this change, viz., the transudation, be prevented. As already stated, by some pathologists the exfoliation of the gastric and intestinal epithelium has been considered to be the essential pathological condition, preceding and causing the transudation.

In opposition to the foregoing view of the pathological character of the disease, the theory of elimination has been revived and advocated especially by Prof. Geo. Johnson, of London. According to this theory, the choleraic, gastro-intestinal effusion contains morbid material which is to be eliminated from the system; hence the vomiting and purging are conservative, and are to be encouraged instead of being arrested. The theory is not sustained by positive evidence, that is, there is no direct proof of the existence of a morbid material in the gastro-intestinal effusion; and the commonly received doctrine which attributes the blood-lesions and the phenomena therewith connected, in a great measure, to the loss of water and other constituents of the blood by means of the effusion into the alimentary canal, is believed to be in accordance with clinical facts. The necessary conclusion to which the theory of elimination leads as regards treatment, viz., that the choleraic effusion is to be encouraged rather than arrested, if the theory be not true, can hardly fail to prove pernicious.[1]

Prof. Johnson attributes the diminution of temperature, the cyanosis, and other symptomatic phenomena, to obstruction of the pulmonary circulation, and states that the lungs are found after death to be notably free from blood. The latter statement is by no means true of all cases; the lungs, in a certain proportion of cases, are congested. The cause of the pulmonary obstruction, according to Prof. Johnson, is spasm of the vessels of the lungs, and this spasm he supposes to be a direct effect of the choleraic poison in the blood. These views are purely conjectural.

Causation.—A special cause is undoubtedly essential to the production of epidemic cholera; ordinary causes of disease, alone, are incapable of producing it. This is a logical inference from the epidemic character of the disease, its remarkably distinctive features, and its great uniformity, as regards symptomatic phenomena, in all places and periods, although the nature and source of the special cause are unknown. Is the special cause a contagious or infectious material, that is, is the disease diffused by means of a virus or an infectious miasm derived from the bodies of those affected with it? To account for the diffusion of the disease on the supposition of its communicability, was the easiest mode, and certain facts favor this supposition. The epidemic, in its migrations, follows routes most travelled; it prevails in thoroughfares and cities; frequently the first case in a new place is an imported case; different members of a household are successively attacked, etc. It is easy to gather isolated facts to support the doctrine of communicability. But surveying the facts on all sides, and weighing the evidence for and against contagion or infection, the con-

[1] The prediction concerning the perniciousness of the treatment has been verified. The use of castor oil in King's College Hospital, in the epidemic of 1866, proved extremely disastrous, and, in the hands of Dr. McNamara, in India, the mortality was fearful. *Vide* London Lancet, 1871, and Am. Journ. of Med. Sciences, Jan. 1872, p. 252.

clusion is to my mind irresistible that the spread of the disease is not due to its being communicated from those affected to others. Without entering into a discussion of this important question, the following are the considerations on which the conclusion just stated rests:—

1. Of those who are brought into contact with, or close proximity to, cholera patients, the proportion who become affected is not larger than that of those who are not thus exposed. This is true as a general statement. In the Report on Cholera in Paris, in 1831, published by order of the French government, it is stated that of over fifty-five thousand persons affected and over eighteen thousand deaths, only one hundred and sixty-four were persons whose duties or profession called them to nurse or prescribe for the sick. These 164 cases were from over two thousand persons employed in the *hospices* or civil hospitals either constantly or temporarily.[1] Hospitals are not foci of infection. At St. Petersburg, of 58 persons employed in hospital, only one had the disease. At Moscow, of 123 persons attached to one hospital, 2 only; and of 253 persons connected with another hospital, only 4 were attacked. In the London Hospital, during the epidemic of 1866, of 100 persons employed in the cholera wards, 5 had the disease. Three of these were nurses who slept outside the hospital. Of 11 laundry women, one had the disease. "No case occurred in the general wards of the hospital, although during the whole period of the epidemic they contained their full number of cases, most of whom came from cholera localities."[2] Facts like these could be multiplied to any extent. Contrast with these the facts with respect to the diffusion of typhus in hospitals!

2. Imported cases in situations where the disease had not previously existed do not lead to its diffusion. Some striking instances which appear to be exceptions to this statement might be cited, but in general it is true that the disease does not spread from isolated cases.

3. The epidemic breaks out in a place almost simultaneously in different situations, without any communication of the cases with each other.[3]

4. It is diffused too rapidly to be propagated by contagion or infection. If contagious or infectious, it must be most highly so to account for the rapidity with which it extends, and the latter is not consistent with other facts.

5. It runs its career in places too soon, and leaves too suddenly and completely for a contagious or infectious disease. Compare its course as an epidemic, in this respect, with typhus, smallpox, or scarlet fever!

6. Efforts to produce the disease, experimentally, by the greatest amount of exposure, by inoculation, tasting the excretions, etc., have failed.

There can be little or no doubt that the special cause may be transported in clothing and other substances after the manner of fomites. Facts might be cited in proof of this opinion; in other words, the disease is *portable*, without being contagious or infectious.

Since the preceding remarks on the causation of cholera were written (1866), the repeated visitations of the disease in Europe and in this country, have given rise to renewed inquiries and speculations respecting the source of the special cause and the manner in which it is diffused.

[3] *Vide* Report, by the author, of the Epidemic at Buffalo in 1849, in Buffalo Medical Journal, vol. v., 1850; also, Report of the New York Metropolitan Board of Health for 1866, page 166; also, Facts relative to the Rise and Spread of the Disease in London and other towns in England during 1848-49 and 1865-66, in Brit. and For. Medico-Chir. Rev., Oct. 1870, p. 483.

The theory advocated by the late Dr. Snow, of London, has been accepted by many, and therefore claims notice. This theory is based on the supposition that cholera, pathologically, is a disease exclusively of the alimentary canal, and that the production of the disease is always attributable to the introduction of a specific virus within the canal. The disease being thus produced, the excreta from the alimentary canal, that is, the matters vomited and discharged from the bowels, contain the special virus, and it is exclusively by means of this virus that the disease is propagated. According to this theory the disease is communicable, and never produced otherwise than by a virus generated within the alimentary canal of those affected. Dr. Snow accounted for the diffusion of the disease by supposing that the virus existing in the excreta of cholera patients is especially liable to be contained in water which is drank, and that it may be contained in the air and thus get into the mouth or nostrils, and thence into the stomach. He supposed that the virus in a dried state may adhere to clothing, and that the disease is in this way portable.[1] The theory of Dr. Snow has been accepted by some with certain modifications. Thus, Thiersch considers that the excreta do not at once contain a virus, but that a special poison is produced by a fermentation or decomposition of the excreta, the process requiring several days and being favored by a high temperature. Again, Pettenkofer supposes that the choleraic excreta only furnish germs which are developed into activity in the soil, various conditions pertaining to the moisture of the soil, the temperature, etc., being favorable, or otherwise, to the production of the poison. It is supposed that the specific matter giving rise to the disease is produced within the alimentary canal, not only in the cases of fully developed or well-marked cholera, but in cases of so-called cholerine, the latter, as well as the former, affection being caused by the same virus. This supposition, of course, involves the conclusion that the diarrhœa which prevails during the prevalence of epidemic cholera, that is, cholerine, is essentially choleraic.

The theory of Snow, with as well as without these modifications, has an obvious bearing on the employment of preventive measures, as contrasted with the doctrine that the special cause is a miasm the nature and source of which are not ascertained, the miasm travelling through the atmosphere, or carried in clothing and other material substances, or diffused by both these modes, and giving rise to the disease either by the co-operation of other causes acting upon those who are attacked, or by finding in certain situations circumstances favorable for its development and increase. According to this doctrine, the special cause being neither of the nature of a virus, nor a miasm generated within the bodies of cholera patients, the disease is not contagious nor infectious. It is, however, true that, accepting this doctrine, the disease is in one sense communicable; the miasm, although not a morbid product, may be transported in clothing. The portability in the manner of fomites may serve to explain the well-known fact that the disease in its progress over the world follows the routes of travel, and seems in its causation to depend sometimes on human intercourse.

After a careful reconsideration of the question of the communicability of cholera, it seems to me that this view of the causation is rendered untenable by the considerations which have been presented. The occurrence

[1] *Vide* Reports on the epidemic Cholera, by Baly & Gull, London, 1854. Exposition of Dr. Snow's Theory by Dr. B. W. Richardson, in London *Med. Times and Gaz.* Oct., 1865; and in *Am. Journ. of Med. Sciences*, April, 1866.

of numerous cases either simultaneously or in quick succession, at points so far removed from each other that there could not possibly be any communication; the rapidity with which the epidemic reaches its climax, and the brief duration of the epidemic, are facts entirely irreconcilable with the theory which attributes the diffusion of the disease exclusively to a virus contained in the excreta, or to an infectious miasm.

Rejecting the doctrine which attributes the causation of cholera to a contagious or infectious material, the nature and source of the special cause of this disease are undetermined. This is a reiteration of a statement which, at the present time, is to be made with respect to many of the special causes of disease. The doctrine that cholera, as well as numerous other diseases, is caused by the introduction into the body of certain cryptogamic or infusorial germs, has heretofore had able advocates.[1] Recently this doctrine has been revived, and zealous pathologists in different countries have engaged in researches relating to it. It has been advocated especially by Prof. E. Hallier, of Jena, who has studied with great zeal the choleraic emanations with reference to the presence of germs and fungi, their supposed sources, and their production by artificial cultivation. Without entering into details, suffice it to say that facts, so far as at present ascertained, do not appear to offer a demonstration of this doctrine, although, rationally considered, it is perhaps most consistent with what is known of the causation of the disease.

Auxiliary causes appear to be essential to the efficiency of the special cause. Epidemics are chiefly confined to large towns, rarely extending into rural districts. It is not probable that the special cause is limited to cities. The prevalence often of mild diarrhœa or *cholerine* throughout the country shows the wide diffusion of an epidemic influence; but the various local causes of disease peculiar to cities give rise to cholera either by acting in conjunction with the special miasm, the latter of itself being insufficient, or by acting as localized conditions which promote the development of the special cause. This view of the causation has an important practical bearing. If the special cause of cholera cannot be destroyed, it may be rendered to a great extent inoperative by means of sanitary regulations which remove auxiliary causes. The epidemic prevails mostly in districts in which the hygienic conditions are most unfavorable, in filthy streets, and among the poorer classes, in overcrowded dwellings. Statistical researches by the Registrar-General of Great Britain show the mortality in London from this disease to be in an inverse ratio to the elevations.[2] Deprivations, intemperance, depressing emotions, over-exertion, fear of the disease, etc., are auxiliary causes in certain cases, aside from the causes which affect the inhabitants of a place or district in mass. The disease has prevailed in all climates and seasons. Feeble persons are more apt to be attacked than the robust. As regards age, no period of life is exempt, but the largest proportion of fatal cases is among persons advanced in life. Excluding old persons, the mortality is largest after adult age, next in early infancy, and last in childhood and youth. This statement is based on an analysis of 18,400 cases.[3]

Diagnosis.—During the prevalence of cholera, there is no difficulty in recognizing it when fully developed, that is, when symptoms denoting

[1] See Holland's Medical Notes and Reflections, and a treatise on the Cryptogamic Origin of Diseases, by the late Prof. J. K. Mitchell. In a *résumé* of later facts and opinions, *vide* Aiken's Science and Practice of Medicine, sixth edition, 1872.

[2] British and Foreign Med-Chirurg. Review, July, 1853.

[3] Valleix, *op. cit.*, tome i.

existing or impending collapse are present. There is scarcely any other disease in which the diagnostic features are so strongly marked. But it is vastly important to recognize it before it has advanced sufficiently to manifest its most obvious, striking characters. The diagnosis is then to be based mainly on the characteristic intestinal evacuations. As soon as the so-called rice-water or choleraic stools are apparent, the patient is to be considered as attacked with cholera. In a very small proportion of cases these evacuations do not occur at all, or not until other symptoms characteristic of the disease become developed. The diagnosis in these cases must be based upon the latter.

Cholera is to be discriminated from simple diarrhœa, or cholerine, which generally precedes it, and which, during the continuance of the epidemic, affects a vast number of persons without eventuating in cholera. It is probable that this premonitory and wide-spread diarrhœa proceeds from the epidemic influence, but cases are not to be considered as cases of cholera when the choleraic discharges and other characteristic symptoms do not occur. This discrimination is important with reference to determining the rate of mortality, and the value of therapeutical measures. The apparent success attending the practice of some physicians, or the employment of certain methods of treatment, may depend on cases of simple diarrhœa or cholerine being reckoned as cases of cholera.

This disease is one of the most insidious in its approaches. Aside from a mild diarrhœa, it gives no warning of the attack. So little are patients conscious of danger, that they often apologize for giving the physician the trouble of visiting them, when a glance suffices to show that they are on the verge of collapse. It behooves the physician, in all cases of simple diarrhœa during an epidemic of cholera, to watch carefully the evacuations with reference to the diagnosis. On the other hand, during an epidemic, physicians are not infrequently called to see persons who, under nervous excitement, imagine that they are about to be attacked, when no symptoms whatever of the disease are present. These have been aptly called cases of *choleraphobia*.

Prognosis.—Of those attacked with cholera, a large proportion die. The average mortality in hospitals varies from one-half to one-third. When developed in hospital wards among patients admitted for other diseases, it proves fatal in the great majority of cases. In private practice, especially among the better classes of society, the mortality is considerably less. In individual cases the prognosis is widely different according to the period of the disease at which the patient is first seen. If seen immediately after the attack, before serious blood-lesions have occurred, the prospect of an arrest of the disease is good. But if the disease have advanced to the stage of collapse, the prognosis is always exceedingly unfavorable. After reaction from the collapsed state occurs, the danger is still considerable, but the cases in which recovery takes place preponderate. The statistical researches of Duchesne show the rate of mortality at different periods of life in the epidemic at Paris, in 1849.[1] The proportion in 1000, in subjects under 5 years, was 148; from 5 to 15 years, 50; from 15 to 30 years, 177; from 30 to 45 years, 254; from 45 to 60 years, 206; and from 60 to 85 years, 162. The mode of dying is, in general, typical of asthenia. Accumulation of liquid in the air-tubes very rarely takes place.

[1] Valleix, *op cit.*

Prevention of Cholera.

The prophylaxis of cholera claims consideration under a distinct heading, and I give it precedence over the therapeutical management, in view of its greater relative importance. In addition to the removal, as far as possible, of all the auxiliary causes of disease which contribute to render the special cause of cholera efficient, the prevention involves prompt attention to the diarrhœa, which, in the great majority of cases, precedes the attack. This premonitory diarrhœa is amenable to simple measures of treatment, and, if effectually treated, there is reason to believe the supervention of cholera is prevented. All physicians who have had much practical acquaintance with this disease will bear testimony, *first*, to the fact that an attack of cholera is generally preceded by diarrhœa, and, *second*, to the fact that an attack very rarely occurs when this diarrhœa receives appropriate attention. Giving the results of my own experience with respect to the facts just stated, in 1849, for the space of three months, I prescribed for as many private patients with the premonitory diarrhœa, or cholerine, as my physical endurance would permit, my practice being chiefly among the prudent classes, and I had, during this epidemic, but 10 cases of cholera in private practice. In only one of these 10 cases did I prescribe for any premonitions, and, in the single case, the prescription was for a slight nausea only. In each of the 10 cases, either the premonitory diarrhœa did not exist, or it was neglected. During another epidemic in 1852, I had about the same number of cases of cholera in private practice; in not a single case had I been called upon to prescribe for premonitory diarrhœa, and I prescribed for hundreds of persons with simple diarrhœa, not one of whom had an attack of cholera. The experience of others would doubtless furnish, in like manner, evidence of the above stated facts, and from these facts the following conclusion may be drawn: Excepting the very small proportion of cases in which cholera is not preceded by diarrhœa, it may with almost absolute certainty be prevented. It needs but a little reflection to see the immense practical importance of this conclusion.

The treatment of diarrhœa during a cholera epidemic is very simple. An anodyne astringent remedy, with regulated diet, rest, and recumbency, suffice. A few drops of laudanum, with camphor, or the camphorated tincture of opium in conjunction with the tincture of kino, catechu, or krameria, a salt of morphia or opium in pill or powder with tannic acid, the acetate of lead, or bismuth and capsicum, may be given in doses sufficient to arrest at once, and repeated often enough to prevent recurrence of, the diarrhœa. Cathartics are on no account to be given. If there be sufficient constipation to occasion inconvenience, the bowels should be relieved by simple enemas.

The great difficulty, as regards the prevention of cholera, is in the prompt application of simple but effectual treatment in all cases of diarrhœa during the epidemic. Very many pay no attention to the premonitory diarrhœa, through ignorance, and not a few of those better informed neglect it, either from recklessness or because they cannot appreciate the fact that a disorder so slight and ordinary can be a precursor of a malady of such gravity as cholera. Public announcements by handbills, articles in newspapers, etc., of the importance of promptly resorting to treatment for diarrhœa, fail in accomplishing the object. The only effectual plan is to organize a sanitary police, and provide for one or two domiciliary visits daily at every house within the limits of the epidemic, the purpose of the visits being to inquire if any one be affected with diarrhœa, to impress

the importance of immediate attention to it, and, when circumstances render it necessary, to supply at once appropriate remedies. This plan, faithfully carried out, would, I believe, demonstrate that cholera is in a great measure preventable. The prevention is effected by arresting at once diarrhœa, as often as it occurs and as soon as it occurs. Abundant proof of the successful operation of the system of house-to-house visitation was furnished by its practical results in London and other towns in Great Britain during the epidemic of 1849.

Another mode of escaping the disease is to remove without the range of its prevalence. Persons not compelled to remain by necessity, or by a sense of duty, should go beyond the limits of the epidemic; and the removal of persons in districts, where, owing to the activity of auxiliary causes, the disease is especially rife, should be enforced, as a sanitary measure, by municipal authority.

The foregoing remarks relate to the prevention of cases of cholera during an epidemic visitation. To prevent the visitation of the epidemic is an object of still greater importance. In this connection the inquiry at once arises, Can the introduction of the disease be prevented by a rigid quarantine, and the suspension of intercourse with places in which the disease prevails? At the present time, neither the affirmative nor negative answer can be sustained by an appeal to facts sufficient to carry the weight of proof. The question is a mooted one, and it is not consistent with the plan of this work to enter into a discussion of it. In view of the fact that many hold to the doctrine which attributes the propagation of the disease to a virus, and of the fact that, assuming the special cause to be a miasm generated without the body, this miasm is probably portable, that is, liable to be transported from place to place in ships, clothing, merchandise, etc., the propriety of adopting certain measures of protection is hardly to be questioned. Ships with cases of cholera on board should be detained at quarantine, and proper disinfecting means resorted to. But the propriety of detaining well persons after thorough ablution, and a change or the disinfection of clothing, may fairly be doubted. Similar precautions, to be complete, should, of course, be extended to communications by land with places in which the disease prevails.

In the absence of positive knowledge, and of unanimity of opinion, respecting the nature and source of the special cause, the employment of disinfectants in the localities in which the disease breaks out is also to be advised. Of all measures first in importance are those which secure, to the fullest possible extent, ventilation and cleanliness. These are not to be supplanted by any or all of the disinfecting articles which are supposed to destroy the special cause by chemical action. Recent experimental observations, however, seem to show that the latter are of vast importance. The agency of disinfectants generally depends on their power to oxidize or deoxidize the substances with which they come into contact. Certain of them are supposed to act by destroying microscopic organisms, either animal or vegetable, and by arresting catalytic or fermentative processes. For disinfecting the atmosphere, chlorine has long been considered a most efficient agent. Ozone, eliminated by means of phosphorus, is another efficient gaseous disinfectant. Bromine belongs in this category. For the disinfection of clothing, the alvine excreta, etc., the compounds of chlorine, creasote, carbolic acid, the permanganates, the sulphite and hyposulphite of soda, the salts of iron and of lead, are to be named. These substances enter into various preparations which have been named after those introducing them, such as Condy's disinfectant, Darby's fluid, Le Doyen's disinfecting fluid, etc. It is generally

agreed that dry heat is one of the most reliable of disinfecting agencies. A temperature of from 200° to 260° Fahr. is supposed to destroy the special cause of this and other epidemic diseases. For general disinfectant purposes on a large scale, charcoal and quicklime are sufficiently reliable, and, from their cheapness, readily available.[1]

Of the measures to prevent the origin and diffusion of cholera, those relating to public health, irrespective of the destruction or arresting the introduction of the special cause, are of the first importance. There is reason to believe that sanitary measures which remove the ordinary causes of disease will prove effectual in preventing this epidemic. Whatever may be the nature and source of the special cause, auxiliary causes seem to be hardly less essential for the production of the disease. Whether the latter act by affording a pabulum for the development and increase of the special cause, or by impairing the ability of the system to resist the action of this cause, we cannot say ; but our ignorance of the true explanation does not render, practically, less important the fact that this epidemic, as a rule, prevails in localities where the ordinary causes of disease are rife. The causes which are most efficient as co-factors are those incident especially to cities or large towns, camps, and all places in which human beings are densely congregated. Deficient sewerage, cesspools, accumulations of filth of every description, overcrowded and unventilated dwellings, underground habitations—these are among the causes affecting public health, which, in some way co-operating with the special cause, lead to the rise and spread of cholera as of other epidemic diseases. These causes may be to a great extent removed by efficient sanitary measures, and epidemics in this way are either warded off or their prevalence greatly curtailed.

The efficacy of preventive measures in arresting the spread of cholera seemed to be strikingly exemplified in the history of the epidemic in New York in 1866 and 1867.

In anticipation of an epidemic visitation, in 1866, the administration of affairs relating to public health was vested in five sanitary commissioners, four being distinguished members of the medical profession. Dr. E. Harris, widely known by his labors in behalf of sanitary science, was appointed Registrar of Vital Statistics; the late Dr. E. B. Dalton was selected as the chief executive officer, with the title of Sanitary Superintendent; and medical inspectors were employed for the different precincts. The measures adopted with a view to arrest the spread of the disease were as follows: The removal, as far as possible, of all localizing causes, the transference of patients to hospitals established in convenient situations, and a prompt resort to efficient disinfection wherever the disease might appear. Under the direction of the able and energetic superintendent, these measures were thoroughly carried out, and the citizens of New York have much occasion for gratitude in the result. As bearing on questions of vast importance in relation to the etiology and prevention of the disease, the facts contained in the subjoined report of the sanitary superintendent, which

[1] *Vide* articles by Dr. Edward R. Squibb, in "The Medical Record," New York, May 1st and 15th, 1866, for details (which cannot be here introduced) respecting the relative value of different disinfectants, their mode of action, and the mode of their employment; and an article by Dr. C. A. Lee, in the same Journal, May 15, 1866. *Vide*, also, an able review, by Prof. Roberts Bartholow, in the American Journal of Medical Sciences, July, 1867; and articles by Dr. Elisha Harris, in "Military Medical and Surgical Essays," edited by Dr. Hammond, and in Report of Metropolitan Board of Health, New York, for 1867.

was kindly furnished at the author's request, are highly valuable. These facts show, in the first place, the development of cholera in different, widely separated situations, under circumstances which render untenable the doctrine of diffusion by means of a virus or miasm derived from the bodies of those affected with the disease; in other words, they show that the breaking out of the disease in different places was not due to the dissemination of a special material contained in the excreta, or to any other mode of communicability. This conclusion is not inconsistent with the portability of the special cause of the disease, nor is it incompatible with an admission of the possibility of the disease being in some cases communicated. The facts show the development of the special cause in connection with the operation of localizing causes, and, in this respect, the facts accord with those observed during the prevalence of the disease at other times and places.

In the second place, the facts contained in the subjoined report go to show that the special cause of the disease may be destroyed by disinfecting agencies. It is in this point of view that the facts are especially valuable. They warrant the belief that, by efficient sanitary regulations as regards the ordinary causes of disease, and by resorting to means adequate to destroy the unknown special cause as soon as cases occur in any locality, the epidemic prevalence of cholera may be restricted within narrow limits.

The following report by Dr. Dalton embraces statistics of the disease in New York and Brooklyn:—

"The first case of cholera in New York occurred on the first of May, the second on the following day, and a third on the sixth (1866). Subsequently no case occurred until the fourth of June, since which time there have been more or less cases every day.

Number of cases in New York outside of public institutions, to Sept. 22d .	751
Number of cases in New York in public institutions, to Sept. 22d . . .	421
Number of cases in Brooklyn outside public institutions, to Sept. 15th . .	650
Number of cases in Brooklyn in public institutions, to Sept. 15th . . .	87

"At first the cases occurred in localities widely separated, but, as the season advanced and the cases became more frequent, they occurred, not successively in the same localities, but, with comparatively few exceptions, within the limits of various circumscribed localities, which latter were themselves widely separate from each other, the result being, that individual cases were proximate, while the groups were widely separated.

"These localities, within the limits of which the mass of cases have occurred, were, without exception, insalubrious. A few isolated cases have occurred where such was not the fact.

"The original development of the disease was not distinctly traceable to any particular emigrant passenger, nor any particular lot of baggage or merchandise; but it followed the arrival in our harbor of infected emigrant ships.

"There is no evidence that the disease was carried from one locality in the city to another, excepting that individuals have left an infected locality apparently well, and subsequently died of cholera in an uninfected locality, but without infecting other persons. It seems probable that the disease occurred in each locality independently.

"Experience here furnishes evidence that the dejections are one means of propagating the disease, instances having occurred where persons have been taken with it soon after having washed bedding, etc., soiled by a cholera-patient; but such persons had been subjected to the same original causes as the one by whose dejections they appeared to become infected.

The mass of evidence, however, is negative, depending upon the apparent controlling influence of disinfection of privies, vessels, and material used by cholera-patients.

"Every house in which the disease has been known to exist has been disinfected. Sulphate of iron in saturated solution, or scattered dry in wet places, has been used for privies and all vessels containing dejections. Solution of permanganate of potassa—one ounce to five gallons—for bedding and clothing, the latter being boiled in such a solution for two hours and then reboiled and washed in pure water. For purifying the atmosphere, chloride of lime has been freely scattered about the floors, and often chlorine has been slowly set free in the room of the patient by adding sulphuric acid to a mixture of chloride of sodium and binoxide of manganese. Where entire fumigation of the house has been necessary, it has been done either by chlorine rapidly set free by adding sulphuric acid to chloride of lime, or by sulphurous acid set free by burning sulphur.

"Disinfection of the immediate surroundings of the patient has frequently been apparently sufficient, though in many instances a second and sometimes a third case has occurred in the same house.

"Fumigation, either with chlorine or sulphurous acid gas, has, with two exceptions, been followed by complete immunity from the disease. In one of the exceptions a case occurred some five weeks subsequent to the fumigation, and in the other five days.

"No confidence is felt in any particular line of treatment for the control of the disease. The ordinary means for alleviating the suffering of the patient have been used with success, and the subcutaneous injection of morphia has been efficacious in preventing the recurrence of cramps."

The efficacy of the preventive measures employed in the manner described in the foregoing report is confirmed by the experience of the subsequent year, viz., 1867. The facts relating to the disease in this year are concisely stated in the following extract from the Report of the Board of Health: "Twenty-seven deaths from cholera have occurred during the past year (1867) in the city of New York, five in the city of Brooklyn, and eighteen at the military post in the harbor. The disease has not excited public alarm, and never approached the character of a general epidemic. The means used to combat it were the same as those employed in the year 1866. Wherever a case occurred, the Disinfecting Corps cleansed the buildings, or fumigated them with sulphur, and destroyed the clothing if it could not be disinfected by boiling water or the permanganate of potash. The experience of another year has confirmed the opinion that active interference, by means of disinfectants, is the surest way to control and arrest this terrible disease."

The efficacy of sanitary measures and disinfection in promptly arresting the prevalence of cholera was strikingly exemplified by the history of an outbreak of the disease at the workhouse on Blackwell's Island in 1866. The measures were instituted by my colleague, Prof. F. H. Hamilton; and the following are the facts contained in the history as given in a letter to the Registrar of vital statistics: The first case occurred in the workhouse July 28th, and the last case was on August 6th. During these nine days of about 800 inmates 123 died. The explanation of the rapid propagation and fatality of the disease was believed to be mainly confinement and crowding. Prof. Hamilton undertook to drive out the disease in from three to five days, and succeeded by means a summary of which is contained in the following extract:—

"The inmates were distributed as far as the vacant places in the build-

ing would permit; the cell-doors were left open at night; the night-buckets were supplied with disinfectants and left outside; the women's cooking-rooms were converted into hospital wards, and the women were kept out-of-doors from morning until night; corn-meal and molasses were taken from the diet-table; coffee, tea, and vegetables were added; at night each inmate was required to take, whiskey one ounce, water three ounces, tincture of capsicum fifteen drops. [These people are our city vagrants, and probably are habitually intemperate.] A variety of disinfectants were employed freely and constantly in every vessel and closet which received the excreta; even the excreta from the stomach were disinfected immediately after they were received into a vessel or fell upon the floor; stoves were placed in each hospital ward to insure a draught; all windows were kept open day and night; the clothing taken from cholera patients was sent directly to the boilers; a ward was established for patients with the diarrhœa, and the value of this measure is shown by the fact that of the large number received into this ward only one died. It was difficult, however, to persuade these poor creatures to report themselves at this stage of the disease."

"Of fourteen house-physicians and surgeons employed in the several buildings, some of whom have been in constant attendance upon the sick, not one suffered from the epidemic."

Finally, with reference to the prevention of cholera, facts warrant the belief that, by disinfecting vessels with cholera patients, the prompt disinfection of the places in which successively the disease breaks out, the immediate arrest, by simple measures, of diarrhœa, the accomplishment of the latter object, in all cases, being secured by house-to-house visitations, and the efficient carrying out of sanitary measures for the people at large, together with proper attention to personal hygiene, epidemics may be effectually controlled.

Treatment.—To consider the host of remedies and therapeutical measures which have been advocated as more or less efficacious in the treatment of this disease would require not a little space. There are but few articles in the materia medica which have not been tried, even including antimony and drastic purgatives. Much injury has doubtless been done by over-medication under the idea that the treatment, as regards activity, must be proportionate to the amount of danger from a disease. On the other hand, many of the remedies which have been employed exert little or no effect either for good or harm. During the epidemic of 1849, a writer in one of our medical journals gravely announced as a remedy, hogs' bristles or the hair from a cow's tail burned to a cinder! It would be unprofitable to devote space to the consideration of the great variety of practice which the literature of cholera affords. There is no known remedy which is to be considered as a specific, yet there is reason to believe that the disease is frequently controlled by efficient treatment, and, when not arrested, the recovery may depend on the judicious employment of measures for that end. I shall limit myself to a brief statement of the principles of treatment which my own experience and reflections have led me to regard as most consistent with our present knowledge.

The treatment is to be considered as applicable to the different stages, viz., before collapse, during the collapsed stage, and after reaction. Prior to collapse, the paramount object is the arrest of the intestinal effusion. This effusion is the first appreciable link in the chain of morbid sequences,

and, if promply arrested before it has proceeded so far as to affect seriously the blood and circulation, the patient is usually safe. The remedy on which most dependence is to be placed in effecting this object is opium. Some form of opiate is to be given promptly in doses sufficient to effect the object. The form of opiate is to be chosen with reference to promptness of action and the probability of its being retained. Opium in substance is unsuitable from the comparative slowness with which it is absorbed. Laudanum, the acetated tincture, or an aqueous preparation, is to be preferred. But the article which I have been led to regard as the most eligible is a salt of morphia, administered by placing it dry upon the tongue. In the endeavor to effect the object of treatment in this stage, moments are precious, for there is always danger that, if the object be not promptly effected, the patient will fall into the collapsed state. The opiate should, therefore, be given at once in a full dose. A grain of a salt of morphia is rarely, if ever, too large a dose for an adult. A physician should, if possible, remain with the patient. If the first dose be quickly rejected, a second should be instantly given. The doses are to be repeated at intervals of from half to three-fourths of an hour, until the dejections and borborygmi cease. If, owing to the occurrence of vomiting, the administration by the mouth be ineffectual, it should be given by the rectum; and in cases in which the symptoms are urgent, both modes of administration should be resorted to. The system, even in this stage of the disease, is not readily affected by opiates thus given. In view of the importance of the object, if it be necessary in order to effect it, some risk of inducing narcotism is justifiable; but if the administration be in the hands of the physician, and the effects of the doses watched with care, danger from this source may generally be avoided. The practical point is to employ the remedy freely and promptly so as to effect the object, bearing in mind the fact that the delay of half an hour or an hour is often fatal. Relying upon the opiate, it is best not to add other remedies, lest by increasing the bulk of the doses they will be more likely to be rejected. A full dose is preferable to small doses frequently repeated, because the effect within a short space of time is greater, and the remedy is more likely to be retained. Aside from the rejection of the remedy, vomiting is, if possible, to be prevented in view of its purtubatory effects. The patient, in this stage, should be restricted to a very small quantity of water, or spirit and water, given at short intervals, or to small pieces of ice. Perfect quietude is important. He should not be permitted to get up to go to stool, and he should be urged to resist, as much as possible, the desire to evacuate the bowels. Frictions, the warm bath, sinapisms, etc., in this stage, are of doubtful expediency.

I have repeatedly succeeded in arresting the disease by this plan of treatment, and when arrested before proceeding to the stage of collapse, the recovery is usually speedy. Regulated diet, rest, with perhaps a tonic remedy, suffice for the cure. The bowels should be allowed to remain constipated for several days, and then, if movements do not spontaneously occur, simple enemas will probably be sufficient; if not, a little rhubarb or some other mild laxative may be given. I believe no other plan of treatment promises more than this, but it is not to be expected that it will always prove successful. It will fail, or rather it is not available, when, owing to the persistent vomiting and frequent purging, the remedy is not retained sufficiently long to exert its effect; and it is not available when, owing to the great rapidity of the transudation, the state of collapse occurs so quickly that there is not time enough to obtain a remedial effect. These difficulties are equally in the way of success from any remedies.

The foregoing remarks on the treatment prior to the phenomena of collapse were written before the hypodermic method of administering opiates and other remedies had come into vogue, and the inquiry has arisen whether, by means of this method, the opiate plan of treatment of cholera, in the first stage, may not be carried out more efficiently than by giving opiates by the mouth or rectum. Considering the vast importance of the promptness of the effect of opiates, and the uncertainty attending their administration by the mouth or rectum, owing to their rejection by vomiting or purging, and the difficulty of absorption if they be retained in the alimentary canal, the hypodermic method seems to offer a great advantage as regards speediness and reliability of effect. The hypodermic injection of Majendie's solution of morphia was employed in a large proportion of the cases which came under my observation in 1866. The vomiting, purging, and cramps were generally arrested promptly by this measure; recovery, however, followed in a very small proportion of cases. So far as my experience goes, it affords evidence of the efficiency of the measure with regard to the immediate objects, viz., the arrest of the vomiting, purging, and cramps, but it does not afford proof of its curative efficacy. With regard to the latter, the character of the patients is to be borne in mind, nearly all who were seen in the first stage being inmates of the hospitals, and many being affected, when attacked with cholera, with some serious chronic disease such as phthisis, Bright's disease, etc. The value of the hypodermic method of employing the opiate plan of treatment, as a curative measure, remains to be ascertained by a more extended clinical experience embracing a more favorable class of cases. The hypodermic injection of a solution of morphia, in this disease, is to be employed with circumspection. Narcotism is sometimes induced by an amount much below that which might be given by the mouth without risk. I have known a little less than a grain, given in two injections, with an interval of two hours, to produce deep narcotism. The tolerance of opiates in large doses by the stomach or rectum is not a criterion of the quantity to be injected beneath the skin in epidemic cholera.

Injections of brandy and a strong tea-infusion were used considerably, with apparent efficacy in arresting the evacuations and preventing collapse. The proportions used were half an ounce of brandy and two ounces of the tea-infusion, the injections being repeated every half hour, every hour, or after longer intervals, according to circumstances.

In the stage of collapse, the plan of treatment indicated prior to this stage may prove not only ineffectual, but hurtful. It is still an object to arrest intestinal transudation, if it continue; but to employ opiates very largely for this object may not be judicious with reference to the recuperative efforts of the system. The symptoms in this stage are due, mainly, to the damage which the blood has sustained in the loss of its constituents from the transudation which has already taken place. Opiates may be given, and, owing to the remarkable degree of tolerance under these circumstances, they may be given in considerable doses, but much care should be observed not to induce narcotism. They should be given by either the mouth or the rectum; never, in this stage, by the hypodermic method. Astringent remedies, if the stomach will retain them, may be added, such as tannic acid, the acetate of lead, bismuth, etc. If, however, these or other remedies provoke vomiting, they will be likely to do more harm than good. Remedies to allay vomiting may be tried, viz., the hydrocyanic acid, creasote, and chloroform. Niemeyer extols the application to the abdomen of compresses wet with cold water.

In a large proportion of cases, after collapse has taken place little can be done with much hope of success. Even if the vomiting and purging cease, recovery may not follow. The blood may have been damaged irremediably. Under these circumstances it is plain that active treatment can effect nothing. Recovery, however, in a certain proportion of cases, takes place, and under a great variety of treatment. It may take place when no treatment is pursued. My first case of cholera, in 1849, illustrated the fact just stated. The patient was brought into hospital completely collapsed. I remained with him several hours, and resorted to various therapeutical measures. At length all measures were discontinued. He was allowed to drink abundantly of cold water, under the impression that the case was utterly hopeless, and, therefore, the indulgence could do no harm. Much to my surprise, after an absence of several hours, I found the vomiting and purging had ceased and reaction was coming on. He recovered rapidly. I have been led to doubt whether, in general, active treatment effects much for the advantage of the patient in the collapsed stage of cholera, and I cannot doubt that it is often prejudicial. The object of treatment in this stage, aside from the arrest of vomiting and purging, is to excite and aid the efforts of nature in restoring the circulation, together with the functions dependent thereon. The measures to be employed for this object are external heat, stimulating applications to the surface, diffusible and other stimulants, and alimentation.

The application of heat may be made by means of warm blankets or bottles of hot water placed near the body. The more active modes of applying heat are of doubtful propriety. I have never seen benefit from the warm bath, or the application of steam or hot air. It is not desirable to excite perspiration, and, if perspiration occur, it should be wiped away with warm dry cloths. Violent friction does more harm than good. The surface may be gently stimulated with sinapisms or the tincture of capsicum. Diffusible stimulants, in the form of spirits and water, should be given as freely as the stomach will bear, always recollecting the risk and the evils of inducing vomiting. It will be most apt to be retained, if given in small quantities at a time, and often repeated. If vomiting be provoked by either drinks, remedies, or aliment, more or less injury is done. The ethers, stimulants such as capsicum, the essential oils, cardamom, ginger, etc., are appropriate if they be grateful to the stomach and retained. Concentrated nourishment—essence of meat, chicken-broth, and milk—is to be given in small quantities at a time, provided the stomach will retain it. It is doubtless desirable to introduce liquid into the system as far as possible. The only objection to the free ingestion of water is the risk of provoking vomiting. Small lumps of ice should be freely allowed.

If the patient emerge from the collapsed state, the indications are to support the system by the moderate use of stimulants and by alimentation; to restore the function of the kidneys by diuretic remedies and mucilaginous drinks, bearing in mind that uræmia belongs among the dangers of this stage; to restrain diarrhœa, if it occur, by anodynes and astringents; to strengthen by tonics, and to palliate, by appropriate remedies, the various symptoms which may arise.

CHAPTER IX.

INTESTINAL WORMS.

Ascaris Lumbricoides. Ascaris or Oxyuris Vermicularis. Tricocephalus Dispar. Anchylostoma Duodenale. Ascaris Alata. Tæniæ. Trichina Spiralis.

OF the various *entozoa*, helminthi, or parasitic animals which dwell within the human body, several are developed in the intestines. They give rise to more or less disturbance, and are properly enough considered in connection with the functional disorders of the alimentary canal. I shall treat of intestinal worms only in so far as concerns the practical duties of the physician. The study of these and other parasites, as belonging to comparative anatomy and physiology, and as a branch of zoölogy, is highly interesting, and has led to valuable practical results, but other points than those which relate directly to them as morbid conditions would be here out of place.

The intestinal worms of frequent occurrence are the *ascaris lumbricoides*, lumbricoid or round worm, and the *ascaris vermicularis*, thread or seat worm. The worm known as *tricocephalus dispar* is probably sufficiently common, but of little or no practical importance. The different species of *tænia*, or tapeworm, are of rare occurrence in this country, but constitute an important affection. These different worms will be noticed under distinct heads. And, as appropriately classed among the intestinal worms, because they are received and developed within the alimentary canal, the *trichina spiralis* will be considered in this connection.

Ascaris Lumbricoides.

With this worm every young physician soon becomes familiar. It resembles the common earth-worm. It is the most common of all the intestinal worms. It varies in length from six to sixteen inches. It is of a whitish or yellowish color; the body is round, tapering toward each extremity, and the mouth is surrounded by three tubercles. The sexes are distinct.

The common lumbricoid worm inhabits the small intestine. It rarely exists in early infancy, and is most common between the ages of three and ten. It is not very uncommon in adults, but is extremely rare in old age. This species of worm is not usually solitary. In different cases the number of lumbrici varies greatly. Sometimes the number is very great, and in autopsical examinations they are occasionally coiled together so as to form balls or masses of considerable size. Cruveilhier cites a case in which over a thousand were found after death. They are not infrequently brought into the stomach by acts of vomiting and ejected from the mouth. They may find their way into the nares, and they have been known to pass into the Eustachian tube, frontal sinus, and larynx. They may migrate from the intestine into the biliary ducts and gall-bladder. In a subject dead with lumbar abscess connected with caries of the vertebræ, I found a great number within the hepatic ducts, some extending along the ducts, and others coiled up. They may possibly give rise to hepatic abscess. They may penetrate into the pancreatic duct. They have been found in

the peritoneal cavity and in abscesses within the abdominal walls. In these cases they doubtless escape through perforations caused by ulceration or sloughing incidental to other morbid conditions; it is not probable that the worms ever perforate the intestines, as was formerly supposed. They have been observed to escape from the body through fistulas communicating with the intestinal canal.

The symptoms denoting the presence of these, or other worms, within the intestinal canal, are obscure. A host of symptoms having little or no significance have been enumerated by writers. Nothing is more common than the passage of lumbrici from the stomach or bowels when there had been no symptoms of disorder. The morbid effects have heretofore been greatly exaggerated. These worms, it is probable, very rarely give rise to serious results except when they migrate into the biliary or pancreatic ducts, the Eustachian tube, or the larynx, and these migrations are exceedingly infrequent. There is no foundation for the belief that they give rise to a form of fever, as implied by the term *worm fever*. They are not infrequently, in cases of fever, passed from the bowels, and found in the intestines after death; but their presence is merely a coincidence. That they may give rise to convulsions, epileptic paroxysms, chorea, and other affections of the nervous system, as is generally supposed, must be considered as by no means established.

Symptoms generally regarded as denoting these worms are colic pains, tumefaction of the abdomen, impaired appetite, excessive flow of saliva, diarrhœa, itching of the nose, swelling of the face, offensive odor of the breath, disturbed, dreamy sleep, and grinding of the teeth during sleep. It is never prudent for a physician to declare positively that a child between three and ten years of age has not worms, for he is liable to be convicted of error by the operation of a vermifuge given without his sanction; but the only readily available diagnostic proof is the presence of one or more in the stools. When more or less of the above-named symptoms are present, a brisk purgative may be given, and the stools examined, with reference to diagnosis. If one or more worms be passed, it is proper to act as if there were others remaining. According to Davaine,[1] a microscopical examination of feces will show the characteristic ova, if lumbrici be present. He states that their ova are readily recognized, and hence the diagnosis may be made positive in this way. Practitioners in general, however, will be satisfied to base the diagnosis upon other facts.

The lumbricoid worm is propagated by ova. The body of a female lumbricus contains a vast number of eggs, estimated by Eschricht to be sixty-four millions. These ova are discharged with the feces. The observations of Davaine and others show that their vitality is retained for many months. Their ingress into the alimentary canal is probably by means of water containing them; and, finding in the small intestines favorable conditions, the production of the worms takes place. That special conditions are required may be inferred from the fact that these worms are so common in certain periods of life, and so infrequent at other periods. As regards the nature of the conditions, we have no positive knowledge; mucus in abundance is supposed to be the nidus for their production.

The expulsion of lumbricoid worms is generally effected without difficulty. Premising a brisk purgative, which is sometimes alone sufficient,

[1] Traite des Entozoaires et des Maladies Vermineuses de l'Homme et des Animaux Domestiques, 1860. The reader is referred to this work as treating of entozoa minutely and comprehensively.

an anthelmintic remedy is to be given for several successive days. Of the various anthelmintics, those best suited for the destruction of these worms are chenopodium or wormseed, santonin, and spigelia or pinkroot. Santonin is most easily administered, and perhaps as effective as the other articles. The dose is from 3 to 6 grains, repeated three or four times daily, given either mixed with sugar, or made into *dragées* or troches. The oil of wormseed is the most convenient form of this remedy. From 5 to 10 drops may be given three times daily mixed with sugar or in an emulsion. The pinkroot has long been relied upon as an efficacious remedy. The infusion may be used, but the fluid extract of spigelia and senna is the most eligible form, the dose being from 1 to 4 drachms three times daily. Tenacetum or tansy, and absinthium or wormwood, are doubtless efficacious remedies. All these remedies act toxically, that is, by poisoning the worms. After two or three days, a brisk purgative should be given. If with this treatment no worms be discharged, their non-existence may be inferred. If worms be brought away by this treatment, it need not be continued or repeated unless, from the continuance or recurrence of symptoms denoting disorder, it be inferred that their expulsion is not complete. The absence of the ova in the stools, according to Davaine, may be relied upon as proof positive of the absence of the worms.

With a view to preventing the ingestion of the ova of lumbrici, attention should be directed to the purity of the water used as drink. Water from shallow wells in the neighborhood of dwellings and small rivulets should be avoided. Filtration would probably prove effectual in the way of prophylaxis. Davaine states that it is not common in Paris for children and others to be affected with this worm, a fact which he attributes to the custom of using filtered water.

Ascaris Vermicularis.

This worm, called also *oxyuris vermicularis* and commonly known as the thread, pin, seat or maw-worm, inhabits the large intestine, and chiefly the rectum. It very rarely migrates into the small intestine. The size is very small, as indicated by certain of the names in common use; the length varies from two to five lines. The vermicular ascarides frequently exist in immense numbers, and they are sometimes voided in large masses or balls agglomerated by mucus. They occur chiefly in young children, but they are not extremely uncommon at all periods of life. I have met with several examples of their occurrence in aged persons.

These worms occasion pain in the rectum, tenesmus, and, more especially, pruritus at the anus. The latter symptom, which is often due to an herpetic eruption in this situation, should always excite suspicion of the presence of these parasites. The itching is apt to occur in paroxysms, and is particularly troublesome at night. Excitation of the sexual organs is apt to occur with seminal emissions, and it is stated that the habit of masturbation, in either sex, may originate from this source. In girls the worms sometimes migrate into the vagina, and occasion pruritus with leucorrhœa. The diagnosis is made without difficulty. On examination of the stools, the worms are seen, in greater or less numbers, adhering to the feces; and on an ocular inspection of the anus they may generally be discovered. It is doubtful if they ever lead to any serious disorders, but, owing to the irritation which they occasion, and loss of sleep, the general health may become more or less impaired.

The treatment is simple and efficacious, but it may require a certain amount of perseverance. The same anthelmintics may be employed as for the destruction of the lumbricoid worms, and given in the same way. Purgative remedies are to be given from time to time. In addition, enemas of cold water, or salt and water, are to be administered once or twice daily. These are to be continued for a fortnight, or longer, until all the local symptoms disappear. The treatment by enemas will frequently alone prove effectual. Various remedies in enemas have been advised, such as wormwood, vinegar, empyreumatic oil, assafœtida, camphor, sulphuret of potassa, etc., but it is very rarely the case that simple water or salt and water, in conjunction with the other measures, will not suffice. Injections of a weakly solution of carbolic acid can hardly fail to prove efficacious. The irritation or slight inflammation about the anus, which is sometimes caused by the presence of these worms, may be relieved by the application of a soothing unguent, or the daily injection of a little almond or olive oil.

Tricocephalus Dispar.

This worm, as the name tricocephalus denotes, is characterized by the hair-like appearance of the cephalic extremity. It is from an inch and a half to two inches in length. The capillary portion forms about two-thirds of its length. As in the lumbricoid and vermicular species, the two sexes are distinct. It inhabits the cæcum especially, but is sometimes found in the colon, and, very rarely, in the small intestine. The propagation is by ova, which, according to Davaine, are readily recognized by means of the microscope in the dejections. The parasite is found frequently, when sought after, in the bodies of subjects of all ages dead with different diseases. Some years ago, when engaged in examining bodies dead with typhoid fever, I was led to examine the cæcum for it, and I rarely failed to find one or more. It is not positively known that its presence gives rise to disorder. Barth, of Paris, has reported a case in which death took place with the symptoms of meningitis, and after death no lesions were found within the head, but the intestines contained an enormous quantity of worms of this species.[1]

The foregoing species of intestinal worms belong in the class styled by helminthologists, *helminthes nematoides*, or cylindrical worms. Belonging to this class is a worm called *anchylostoma*, or *sclerostoma duodenale*, which has been observed in Milan and Egypt. Existing in the duodenum in great numbers, it has been supposed to give rise to the affection known as Egyptian chlorosis, by piercing the walls of the intestine and occasioning hemorrhage, from the great number of minute punctures, sufficient to produce anæmia. With our present knowledge, this parasite has no practical importance in this country.[2] Another worm belonging to this class was described by Bellingham under the name *ascaris alata*, called also *ascaris mystax*, and said to infest the domestic cat.[3] This, as regards its practical importance, is in the category with the tricocephalus dispar.

Tæniæ or Tapeworms.

On the natural history of tæniæ, constituting the class *cestoidea*, in helminthology, and commonly known as tapeworms, much light has recently been shed by the researches of Küchenmeister, Von Siebold, and others. The sources of these parasites seem to have been ascertained. Referring the reader to other works for a full account of these researches, suffice it to say, that different varieties of tænia have been shown to be the cystic entozoa known as *cysticerci* and *echinococci*, in a state of maturity or complete development. A cysticercus is an immature or undeveloped tapeworm. Different varieties of cysticerci are found in the solid parts of different animals, and each variety, received into the alimentary canal of another animal, and finding there favorable conditions, becomes a perfect worm or tænia, each kind of cysticercus becoming a particular kind of tænia. A cysticercus, on the other hand, is the product of the ovum of a tænia. The eggs of the tænia, passing out of the body, finding their way into the bodies of men and other animals, and probably entering into the circulation, are transported to, and fixed in, solid parts, where they become cysticerci. The latter, so long as they remain in solid parts, reach only a certain stage of development; if, however, the parts containing the cysticerci are eaten by another animal, they attain to their complete development in the alimentary canal of the latter. Thus a particular cysticercus found within the liver of the rat, if eaten by the cat, is developed into the kind of tapeworm frequently found in the intestine of the latter; and the ova from this tapeworm received into the body of the rat gives rise to the kind of cysticercus found in the liver of this animal. The ova from the tænia of the dog, received into the body of the sheep, becomes the cystic entozoon, called *cænurus cerebralis*, found in the brain of the latter, which, if eaten by the dog, becomes the tænia found in the intestine of this animal. These highly interesting, and, in a practical view, important facts, appear to have been fully substantiated by accurate observation and experiments.

The tænia or tapeworm is distinguished, as these names import, by its ribbon-like form. It is composed of numerous segments or joints, each one of which, after it attains to its full maturity, is provided with male and female generative organs. Several varieties have been found in man, but, as regards medical practice, the discrimination is not of much importance, the same measures of treatment being alike applicable to all. In the vast majority of cases, the tænia developed in the human intestine is one of three kinds; it will suffice to notice these. In this country, of the three kinds of tænia, the one which is found oftenest is commonly known as the *tænia solium*, or solitary tænia, so called because it is supposed always to exist singly. This is true as a rule, with some exceptions; two or more tænia have been observed together, but instances are exceedingly rare. The tænia solium varies in length from four or five to thirty-five feet, the number of segments or joints varying from 800 to 1000. Toward the head it becomes attenuated, forming a thread-like neck of considerable length, and in this portion there are transverse markings or rugæ, but no visible joints. The joints succeeding the neck are about as long as they are broad, but lower the length is twice or thrice the breadth. From the resemblance of these joints to the seeds of a gourd, the worm has been called *vermis cucurbitinus*, or gourd worm. The generative foramina are placed near the middle of one of the margins of each joint, and are generally alternate. The head is very small, hemispherical or triangular in form, and, under the microscope with a low power, it is

found to present four projections or suckers, and a double row of hooklets, numbering 12 or 15 in each row; the latter are sometimes wanting.[1] The joints of the inferior part are being constantly thrown off, and are passed almost daily by stool. These exfoliated joints contain an immense number of ova. Bennett quotes an estimate of the number of ova in the tapeworm of a cat to be 12,500,000. It is fortunate that worms are not developed from the ova within the alimentary canal!

The second variety, called *tænia mediocannellata*, has not until within late years been generally recognized as distinct from the tænia solium; and the relative frequency of its occurrence is not as yet ascertained. The generative foramina are situated alike in both varieties; but the joints are longer and thicker, and the head has four suckers without hooklets.

The third variety is commonly known as the *tænia lata*, or broad tapeworm, reckoned by some helminthologists as a species distinct from the true tænia, and named *Bothriocephalus latus*. This worm is distinguished from the tænia solium by the breadth of the joints, which are broader than long, by the situation of the genital orifices, which are in the middle of the joints, and by the different conformation of the head. The head is unprovided with hooklets, and hence this and the second variety are distinguished as the unarmed tænia, while the tænia solium is said to be armed. The form of the head is elongated, and, instead of suckers, it has two lateral longitudinal depressions or fossæ; hence the name *bothriocephalus*, from βοθριον, a small pit. This worm may attain to even a greater length than the tænia solium. Like the latter, it is usually solitary. A tænia called Bothriocephalus cordatus, distinguished by the form of the head, is common in dogs and has been found in man.

Of these varieties of tapeworm, the first is the kind commonly met with not only in this country but in most countries. It prevails in England, France, Spain, Austria, Prussia, Greece, and Italy, the tænia lata being almost unknown in these countries. Both occur in Holland, Finland, Norway, Poland, and Sweeden. The latter is the variety chiefly observed in Russia and Switzerland. It is observed that the tænia lata is apt to affect inhabitants living on the coasts of seas, lakes, and rivers, whence it has been inferred that it proceeds from a cystic entozoon existing in fish. The opinion, however, is entertained that the embryos of this worm may be taken into the system in drinking water and developed in the intestines without the intermediate stage of cystic development in the solid parts. The tænia solium is attributed to the ingestion of the *cysticercus cellulosæ*, which is common especially in swine and sheep. It is the presence of this entozoon in large numbers which renders pork "measly." Animal food eaten raw or partially cooked is probably the source of the common tapeworm. Thorough cooking destroys the cysticercus, and the development into the tapeworm does not then take place. It is a matter of observation that pork-butchers and cooks are prone to tapeworm, and it is stated that in Abyssinia, where the custom of eating uncooked meat prevails, nearly all persons, of different ages, become affected with tænia. The production of tænia in children by the use of raw meat as food, in cases of so-called cholera infantum, has been already adverted to. The tænia mediocannellata has been observed in Austria, and some parts of Bavaria; but its geographical history has not been fully determined. The cysticercus, whence it is derived, has been found in veal and beef.

[1] For fuller description, *vide* Owen, in Cyclopedia of Anatomy and Physiology; Aitken, *op.cit.*, 1872. *Vide*, also, Boylston Prize Essay on the Human Cestoids, by F. B. Sturgis, M.D., Cambridge, Mass., 1867.

The habitat of a tapeworm is the small intestine. When it attains to a great length, it extends into the large intestine, and has been found to reach nearly to the anus. No age is exempt from the liability to its occurrence, but, in the majority of cases, the ages are between twenty and forty years. It occurs oftener in females than in males. Prof. S. G. Armor has reported a case in which an infant five days old passed segments of tænia. Two months after the birth of the child the mother was treated for tænia.[1] The frequency of its occurrence varies much in different countries and in different sections of the same country. The report of the military surgeons of the French army from 1840 to 1848 showed only seven cases among 250,000 soldiers. During a practice of nearly forty years I have not met with more than from thirty to forty cases.

The existence of a tapeworm is not denoted by well-marked diagnostic symptoms. The symptoms attributed to it are vertigo, tinnitus aurium, disturbance of vision sometimes amounting to temporary amaurosis, pruritus at the nose and anus, salivation, disordered appetite and digestion, colic or neuralgic pains in the abdomen, and emaciation. These are symptoms which may be due to other morbid conditions, nor are these symptoms uniformly, if generally, marked in cases of tapeworm. The existence of the worm is often discovered accidentally, and in persons who, prior to the discovery, considered themselves perfectly well. In the case of a young female affected with sciatic neuralgia, I was led to prescribe a full dose of turpentine, and the result was the expulsion of a large quantity of tapeworm, the existence of which had not been suspected. After the existence of the worm is known, disorders of all kinds are apt to be referred to it, and often the imagination creates various morbid sensations. Convulsions, epilepsy, and chorea are supposed to be occasional effects, but clinical observation supplies but little data for this supposition. The pathological effects of the presence of this worm have doubtless been greatly exaggerated. Tapeworms are almost invariably found in the intestines of dogs destroyed for experimental purposes apparently in perfect health.

The diagnosis must rest on the discovery of exfoliated joints or pieces of the worm in the evacuations. This mode of diagnosis is always available. Fragments of the worm are generally passed either daily or at short intervals, and hence it is usually not long before its existence is ascertained. If there be reason to suspect its existence before fragments have been seen, a brisk purgative may be given, and this will be likely to be followed by the expulsion of a greater or less quantity. If an examination of the stools for some time, and especially after the administration of purgatives, fail to discover any portions of the worm, the physician may be satisfied of its non-existence. Persons not infrequently fancy they have a tapeworm. This is one of the notions likely to be seized upon by hypochondriacs, and in some cases the notion becomes a fixed belief of which the mind cannot be dispossessed, becoming, in fact, an insane delusion. Several instances of this kind have fallen under my observation. A few instances are on record in which portions of the worm have been vomited.

With reference to treatment, a point of importance is the natural duration of the life of this parasite. It is undoubtedly long-lived. It is not uncommon for fragments to be passed at short intervals for many years. Cases have been reported in which this was observed for twelve, twenty-five, and even thirty-five years. If an interval of several months elapse

[1] Detroit Review of Medicine, Jan. 1873.

without any fragments being discharged, and subsequently they make their appearance, it is probable that a second worm has become developed. Sooner or later, the worm dies a natural death, and a cure takes place spontaneously. If successive remedies have been used in such a case, the last remedy, of course, gets the credit of having effected a cure. For a cure to be effected with certainty, the head must be expelled. The frequent exfoliation of joints is natural, and if, as an effect of a remedy, or from any cause, a large portion, or even all the body be expelled, reproduction by growth may take place so long as the head remains; it is, however, a matter of observation that the parasite is apt to die when the separation takes place near the head. As positive evidence of a cure, the head is to be sought for, but it is not found in the larger proportion of the cases in which a cure is effected.

Of the remedies to be employed for the destruction of the tapeworm, one of the oldest, and, certainly, in many cases an effective remedy, is the oil of turpentine. It is most likely to be effective if given in large doses. A half ounce may be given in emulsion, with the addition of some aromatic tincture to prevent nausea, this dose being repeated every half hour until two or three ounces are taken, or, sometimes, the whole amount taken at once is well borne. Strangury is an occasional result, but is less likely to occur than when the remedy is given in small doses. After a large dose, the patient feels as if slightly inebriated. This remedy, thus given, may be repeated, if necessary, after intervals of several days. Given in the quantity just stated, it generally acts as a purgative. *Chabert's empyreumatic oil*, which has been much in vogue as a remedy for tænia, is probably efficacious chiefly from the turpentine which enters into its composition, and is much more disagreeable than the turpentine alone. It is stated by Bellingham and others that turpentine, given in moderate doses, and repeated for several successive days, is frequently successful.

The male fern (*filix mas*) is a tænifuge, the efficacy of which rests upon the testimony of many observers of large experience. In my own experience it has proved promptly efficacious. It may be administered in powder, from half a drachm to a drachm being given in divided doses in the course of a few hours; but the oil and ethereal extract are more eligible preparations. The oil may be given in doses of a drachm or two in mucilage, or in gelatine capsules; the dose of the extract is from 20 to 30 grains. Dr. Alexander Fleming advises a drachm of the oil, with mucilage, to be given in an ounce and a half of sweet milk, at bedtime, the dinner and evening meal of the day having been omitted. This mode of administration is advised on the supposition that milk being a favorite food of the worm, it is more effectually poisoned by imbibing the remedy in this vehicle. In the two last cases which have come under my observation (1872) the following course proved successful: No food was taken after dinner, but at night a full dose of castor oil. No breakfast the next morning, but a dessertspoonful of an equal mixture of the liquid extract of male fern and mucilage, and repeated in four hours if the first dose be well tolerated and have no effect. In one of the cases a single dose was sufficient, and the head of the worm was expelled.

Another effective tænifuge is the kousso (*brayera anthelmintica*), the dried flowers of a tree in Abyssinia where tapeworm is exceedingly common. This remedy is said to be relied upon in that country. Within the past few years it has been used with much success in Europe and in this country. Half an ounce of the powdered flowers mixed with water may be given in a dose, both the liquid and sediment being taken.

A remedy recently introduced as a tænifuge into this country is an

emulsion of pumpkin-seeds (*cucurbita pepo*). The emulsion is prepared by pounding a couple of ounces of the seeds in a mortar with half a pint of water, and straining through cloth. This quantity will constitute a dose, which may be repeated for several days. This remedy has proved successful in the hands of a number of physicians in this country. It has the advantage of producing no unpleasant effects, being, aside from its action as a vermifuge, innocuous.

The bark of the pomegranate root (*granatum*) is another anthelmintic remedy which has been found destructive to the tapeworm. A decoction made by boiling two and a half ounces of fresh bark in a pint and a half of water until this quantity is reduced one-half, is the form in which this remedy is to be administered. The whole of the quantity just named may be given in the course of a few hours. It generally produces purging, and not infrequently vomiting. The Kamela, the powder and hairs from the capsules of Rottlera tinctoria, is a powerful anthelmintic which has been found promptly efficacious in cases of tænia. The dose is from one to two drachms given in honey or thick gruel. It acts efficiently as a purgative. This remedy has been given with great success in combination with the ethereal extract of the male fern.

These are the most valuable of the athelmintics which experience has shown to be capable of destroying the tapeworm toxically. The powder of tin (*pulvis stanni*) given in doses of a scruple or more, mixed with honey, has, in some cases, proved efficacious, destroying, probably, the worm by its mechanical action. It is far less reliable than the toxical remedies. Active cathartics, such as calomel and jalap, scammony, gamboge, and croton oil, occasionally succeed, their action, probably, being mechanical. They will generally bring away greater or less portions of the worm, but, alone, they are not to be relied upon for effecting a cure, that is, for destroying the worm. In conjunction with the toxical anthelmintics, they are generally useful.

The success of the treatment will depend much upon accessory measures. The worm is nourished, not by nutriment sucked from the intestinal walls, but from the alimentary contents of the intestine, which enter the body of the parasite by endosmosis. An important part of the treatment, therefore, is to weaken the parasite by starvation. The patient, by way of preparation for the administration of the tænifuge, should abstain from those articles of food which are digested in the small intestine, for at least a day or two. Beef-tea or chicken-soup may be allowed freely. The treatment should commence with a mild purgative, and the administration of the anthelmintic remedy should be followed, after a few hours, by a pretty active purgative. If the treatment prove unsuccessful, the strength of the patient should be restored by a return to a full diet and tonic remedies, and the same plan again repeated, employing the same remedy or selecting another. The treatment is to be repeated, allowing sufficient intervals for recruiting the strength, until a cure is effected. It is to be borne in mind that, if the greater part of the worm be expelled, although the head may not be found, the death of the worm is apt to follow, and the treatment, therefore, need not be repeated, until the discharge of fragments is again observed.

The prophylaxis involves care never to eat meat not thoroughly cooked. In meat much underdone, the cysticerci which may be contained in it are, perhaps, not destroyed. Purity of the water used as a drink may be an important measure of prevention. The use of filtered water is to be recommended. The meat contained in the Bologna sausages is liable to contain living cysticerci.

Trichina Spiralis.

From the discovery of the *trachina spiralis* by Paget and its description by Owen, in 1835, up to a recent date, this parasite had been observed occasionally in the muscles of subjects in the dissecting room, but, in a pathological view, it was not considered to have any importance. Facts, however, accumulated within the past few years, have shown that the introduction and multiplication of *trichinæ* within the body of man may give rise to morbid effects of great gravity, which often prove fatal. Much information has been obtained respecting the natural history of the parasite, the circumstances under which the human body becomes infested by it, and the morbid phenomena which characterize the disease. This information has added to the nosological catalogue a new and highly important affection known as the *trichinal* or *trichinatous* disease, *trichinosis* or *trichiniasis*.

Prof. Zenker, of Dresden, was the first to ascertain the nature and source of the trichinal disease. In a young girl who died after an illness of several weeks' duration, characterized by debility, fever, sleeplessness, abdominal tenderness, great pain in the muscles, and œdema of the lower extremities, numerous trichinæ were found in the voluntary muscles, and in mucus from the small intestines. He traced the origin of the disease to the eating of ham and sausages, which, on microscopic examination, were found to contain in abundance trichinæ. This was in January, 1860. Numerous examples of the newly discovered disease were soon afterward met with, especially in Germany. A large collection of cases occurred on a single occasion in Heldstädt, Prussia, in 1863. Of one hundred and three persons who participated in a hotel dinner, on a festive celebration, nearly all were attacked with the disease, and a large number died. The disease in these cases was traced to a kind of sausage called "Röstewurst," of which most, if not all the guests had partaken. On microscopic examination, the remnants of these sausages, and the pork of which they were made, were found to be swarming with trichinæ, and these parasites were found in abundance in the muscles of the persons affected. Several examples, shortly after this, fell under observation in this country. In February, 1864, several members of a family in the city of New York became seriously ill after eating raw smoked ham, and one of the children died. Dr. Joseph Schnetter examined the ham, and found it filled with trichinæ. Prof. Dalton also made an examination and counted in a muscle $\frac{1}{12}$ inch square and $\frac{1}{50}$ inch thick, twelve trichinæ, which would give, in round numbers, over 85,000 to the cubic inch. A short time afterward, a case of suspected disease from trichinæ came under the observation of Dr. Voss. In order to settle the diagnosis, Dr. V. cut down upon the deltoid muscle of the patient, and removed a portion of the tissue. It was examined microscopically by Dr. Voss and Prof. Dalton, and trichinæ were found in abundance, numbering over 7000 to the cubic inch.[1] These were the first reported cases, in this country, in which the character of the disease was established. The next cases reported were observed by Dr. Krombein and Dr. Dingler, German physicians practising in Erie County, N. Y. They were reported in the *Buffalo Medical and Surgical Journal* (1864), by Dr. Krombein, with remarks by Dr. J. R. Lothrop. Subsequently, April, 1866, in a family consisting of ten persons, in Marion, Iowa, nine

[1] *Vide* Observations on Trichinæ Spiralis, by John C. Dalton, M.D., Trans. New York Acad. of Med., vol. iii. 1864. *Vide*, also, lecture by Prof. Dalton published in the New York Med. Record, April 15th, 1869.

were attacked with trichiniasis after eating raw ham. The member of the family who escaped did not partake of the raw ham, but ate of it freely after it had been thoroughly boiled. Of the nine who were attacked, five died. Portions of muscle from the body of one of those who died, and portions of the ham, sent to Prof. John C. Dalton, and Prof. Austin Flint, Jr., of this city, were found to contain trichinæ in abundance. Prof. Dalton has kindly furnished me the following account of the trichinæ in the specimens examined by him:—

"The trichinæ in the specimen of human muscle from Iowa varied in size. The smallest were $\frac{1}{7\,3}$ of an inch long by $\frac{1}{3\,6\,0}$ of an inch thick; the largest were $\frac{1}{2\,2}$ of an inch long by $\frac{1}{6\,4\,0}$ of an inch thick. The larger worms were much more numerous than the smaller ones. They were not completely encysted, but were all inclosed in smooth fusiform tubes, of indefinite length, with thin walls, containing a semifluid granulated matter. The worms were coiled up, with one or two turns, in the dilated portions of the tubes. In a piece of the muscle, $\frac{1}{1\,2}$ of an inch square, and $\frac{1}{5\,0}$ of an inch thick, I found 29 trichinæ. This would give a little over 208,000 to the cubic inch."

This specimen came from a boy 13 years of age, and showed the state of the infected muscles at about the twentieth day of illness.[1]

Since the date of these cases, several instances of the development of the disease in different parts of the country have been reported.

Repeated experiments have been made of giving to animals pieces of flesh containing trichinæ, from other animals, and the human subject. After the death of animals thus fed, trichinæ have been found in great numbers within the small intestines, and in the muscles. These experiments have elucidated important points pertaining to the multiplication of these parasitic animals within the alimentary canal, and their migration to the muscles throughout the body. In short, the existence of a disease of great gravity, involving much danger to life, produced by the introduction into the system of trichinæ contained in food, may be considered as sufficiently established.

The trichina spiralis belongs in the class *nematoidea*. As found in the muscles, it is coiled up in a cyst containing a granular substance at first, and afterward, calcareous matter. When expelled from the cyst, the parasites are seen to be round worms, $\frac{1}{2\,8}$ of an inch long, and $\frac{1}{6\,2\,0}$ of an inch in thickness. So long as they remain in the muscular tissue, the worms are quiescent. When, however, they are taken into the stomach, and set free by the action of the gastric liquids upon the muscular tissue and the cyst, they pass from the stomach into the intestinal canal, and immediately begin to grow rapidly, attaining to three or four times their former size; they acquire fully developed generative organs, and, in the course of a week to ten days, the female parasites contain living young in great abundance. According to Virchow, each trichina gives birth to 200 young; Gerlach says 400, and Leuckart 1000. The young trichinæ, shortly after birth, penetrate the mucous membrane, and find their way rapidly to the different muscles throughout the body. They appear to select the voluntary muscles for their permanent dwelling-place. It is stated that they have not been found in the muscular walls of the heart. In other than muscular organs they are very rarely found.

Trichinæ are found especially in the muscles of swine; but they have been found in the muscles of various other animals, viz., eels, cats, rats

[1] For a report of these cases by Dr. H. Ristine, of Marion, Iowa, *vide* The N w York Medical Record, August 1, 1866.

and mice, dogs, badgers, hedgehogs and moles. They get into the bodies of swine from their feeding upon the flesh and excrement of other animals infested with these parasites, especially rats and mice. Hence, to prevent trichiniasis in swine, and in other animals which serve as food for man, it is highly important to cut off all the sources of the disease in the diet of these animals. They find their way into the alimentary canal of man chiefly from eating trichinous pork not subjected to processes of cooking sufficient to destroy the parasites. They are not destroyed by salting or smoking, and they may retain their vitality in roasted or boiled meat much underdone. To secure effectually their destruction, every portion of meat which is eaten should have been subjected in cooking to a temperature of 212° Fahr. The custom which prevails among the Germans of eating sausages and smoked hams uncooked involves a liability to the disease. It has been traced to eating pork chops which were underdone in the centre, although sufficiently cooked on the outside. Meat abounding in trichinæ may present no evidence of the fact as regards the gross appearance, especially if a calcareous deposit have not taken place in the cysts which contain them; hence, trichinous meat may be sold and bought without any suspicion of its being unwholesome. The only reliable evidence of the presence of trichinæ in the meat procured for food is afforded by microscopical examination. The trouble, however, of such an examination precludes its being generally resorted to as a means of protection. Moreover, a microscopical examination of a few specimens is not adequate to determine that trichinæ are not present. They may not be found in the few specimens examined, although present in other portions. Hence, this test is only reliable in a positive, not a negative, point of view.

It is of interest to know somewhat of the chances that the pork used for food may be trichinous. A committee of the Chicago Academy of Sciences appointed to make examinations with reference to this point, reported that of 1394 hogs examined in different packing-houses and butcher shops of Chicago, trichinæ were found in 28. It was therefore estimated that, of the hogs brought to the Chicago market, one in fifty is affected by trichiniasis in a greater or less degree. In this report it is stated that in the city of Brunswick, Germany, of 19,747 hogs examined only two were found to contain trichinæ.[1]

After becoming encysted in the muscles the trichinæ retain their vitality for an indefinite time. In a case reported in Virchow's archives, trichinæ were found encysted and alive in portions of muscle attached to a cancerous tumor removed from a patient. The previous history of this case showed conclusively that the patient was affected with trichiniasis twenty-four years before the operation.[2] The flesh of animals, therefore, which have been affected with trichiniasis ever afterward will be likely to contain living trichinæ. Moreover, the flesh of a single trichinous animal may produce trichiniasis in a very large number of persons, so that the disease in its prevalence may present the character of an epidemic.

The disease in swine is manifested by symptoms analogous to those observed in man, viz., diarrhœa, stiffness of the limbs, debility, muscular atrophy, and frequently cough. The affection known in the Western States by the name "hog cholera" is supposed to be trichiniasis.[3]

The clinical history of the disease caused by trichinæ is highly important with reference to an early diagnosis. The primary symptoms relate

[1] Med. News and Library, Philadelphia, July, 1866.
[2] Medical News and Library, Philadelphia, May, 1866.
[3] *Vide* report by Dr. H. Ristine, already referred to.

to the alimentary canal, and are due chiefly to the perforation of the mucous membrane by the newly-produced worms. Abdominal pains, vomiting and diarrhœa characterize the first stage of the disease. These symptoms occur within a week or ten days after the ingestion of trichinous meat, that is, as soon as the young worms have been produced and become developed sufficiently to begin to migrate toward the muscles. It is not difficult to understand that the aggregated punctures of the mucous membrane by these parasites should occasion notable disturbance, when it is considered that the trichinæ which have been found to be contained in a half a pound of meat may be sufficient to give birth, in a few days, to a brood numbering 30,000,000. It is stated that peritonitis may be produced by the passage of worms into the peritoneal cavity.

The secondary symptoms relate to the muscles. Pains resembling those of muscular rheumatism are occasioned by the entrance of the trichinæ in the muscles. Certain of the muscles become contracted, in some cases, and their extension occasions great suffering. Constitutional disturbance, more or less marked, accompanies both the primary and secondary symptoms. The general symptoms are not unlike those of typhoid fever, for which the disease is likely to be mistaken. The temperature in the axilla is raised to from 101° to 106°. Œdema of the face or lower extremities is apt to occur, and sometimes anasarca. Sweating is generally prominent as a symptom. In some of the cases observed by Dr. Ristine, of Marion, Iowa, dyspepsia, cough, and a viscid, orange-colored expectoration, were prominent symptoms associated with physical signs denoting capillary bronchitis. Death takes place in a certain proportion of cases, after a protracted period of suffering and exhaustion, being often preceded by coma. It is stated that life in some cases is destroyed by the impairment of the respiratory muscles from the presence of the parasites. Aphonia is a symptom which exists in some cases, attributable to the presence of trichinæ in the muscles of phonation. The danger, *ceteris paribus*, is proportionate to the abundance of trichinæ generated within the alimentary canal. If the number be not sufficient to cause death from the amount of local and constitutional disturbance which they occasion, recovery takes place very slowly, the illness lasting for several weeks or even months. The trichinæ become encapsulated in the muscles, thereafter remaining quiescent, leaving the muscles more or less impaired. An accumulation of a larger number of cases than is at present practicable, is necessary to furnish data for a complete clinical history of the disease, and for determining the relative proportion of deaths and recoveries.

Diarrhœa and abdominal pains, followed by muscular pains, together with more or less constitutional disturbance, should excite suspicion of this disease. Inquiries respecting food should be instituted, and, if any portion of the suspected meat remain, it should be examined microscopically. The diagnosis may be made still more complete by harpooning some one or more of the painful muscles and obtaining sufficient portions for examination with the microscope. Davaine suggests that the presence of trichinæ in the stools may be ascertained, and the diagnosis in this way rendered positive. If clinical observation should establish the availability of the latter method of arriving at a diagnosis, it would have this advantage, viz., the existence of the disease may be positively ascertained before the trichinæ migrate from the alimentary canal. The practical importance of making the diagnosis thus early, is sufficiently obvious.

It is evident that the treatment of this disease, to be effective, must be employed while the worms are in the alimentary canal. Hence, the impor-

tance of an early diagnosis. It remains to be ascertained whether treatment can be effectively employed in this stage, and to determine the measures most likely to prove effective. The object is either the destruction of the worms or their expulsion from the intestines. Cathartics are indicated for the latter object, but clinical experience has yet to ascertain what toxical anthelmintics are best suited to destroy this parasite. Benzine has been found by Prof. Mosler, of Berlin, to destroy the trichinæ in the intestinal canal when given in doses which are well borne by the patient. Prof. Mosler's method of treatment with this remedy is to have a mixture consisting of two drachms of benzine, an ounce each of liquorice-juice and mucilage of gum-arabic, and four ounces of peppermint water. Of this mixture a tablespoonful is to be given every one or two hours. The efficacy of this remedy in man, however, remains to be established.[1] The carbolic acid is a remedy which should be tried with a view to the destruction of the worms in the intestinal canal. After the trichinæ have left the intestines, the opportunity of destroying or expelling them has passed. Recovery now depends on the ability of the system to endure them until they become encysted. Measures to palliate pain, to restore disordered functions, and to support the powers of life, are indicated, and the success of the treatment will depend on the judicious employment of measures for these ends.

The prevention of this disease is the great practical benefit to be derived from its discovery. The mode of prevention is sufficiently simple, viz., abstaining from meat, more especially the flesh of swine, not thoroughly cooked. The process of smoking, pickling, or salting, cannot be relied upon for the destruction of this worm. Uncooked sausages cannot be eaten without danger. The only security is in the fact that every portion of the meat has been subjected to a temperature of 212° Fahr.[2]

Animals not entozoötic, such as snakes, slugs, and lizards, are not infrequently exhibited to physicians as having passed from the alimentary canal. It is a popular notion that they may live and grow indefinitely within the stomach and intestines, and give rise to a variety of morbid symptoms. In the great majority of cases the statements with respect to the passage of these animals are simply falsehoods, proceeding generally from a morbid exaggeration of that craving to become objects of curiosity and interest, which enters largely into the mental constitution of many persons. In some cases, however, the statements are honestly made, persons being deceived. Prof. Dalton has recently performed a series of experiments to ascertain the duration of life of the common garden slug (*Limax agrestis*) and the water-lizard (*Triton millepunctatus*) after having been introduced within the stomach of a dog. The former were found completely dead at the end of nine and a half minutes, and no traces of them were discoverable when the dog was killed an hour after their introduction. The lizards were found perfectly dead, and about to undergo the digestive process, at the end of fifteen minutes.[3] It is safe to set down most of the cases referred to as cases of either self-

[1] British and Foreign Review, January, 1865, p. 236.

[2] For an historical account of discoveries relating to trichinæ, and of experiments to infect different animals and to destroy the parasite by different medicines, *vide* article by John D. Jackson, M.D., in the Am. Jour. of Med. Sciences, January, 1867.

deception or imposition. Maggots, however, have been known to be discharged from the nasal cavity, the mouth, and the rectum. They may be developed in the nasal cavity from ova inhaled; but they may be developed in great numbers within the alimentary canal, the ova having been ingested with food or drink.

CHAPTER X.

Acute General Peritonitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Partial Peritonitis. Chronic Peritonitis. Hydro-Peritoneum.

THE peritoneum in structure and functions does not differ materially from other serous membranes. This, like other serous membranes, may be the seat of inflammation. Inflammation here, as elsewhere, may be acute, subacute or chronic. The whole or greater part of the membrane may be inflamed, and the inflammation is then said to be general; or the inflammation may be more or less circumscribed, and is then distinguished as partial. Inflammation of this membrane, agreeably to the nomenclature of inflammatory affections, is termed *peritonitis*, and this name is in common use. In treating of peritonitis, it will be convenient to consider separately acute general peritonitis, partial peritonitis, and chronic peritonitis. Some writers divide the disease into several varieties, according to its different causes or the circumstances under which it is developed. It will suffice to notice these diversities under the head of causation. Occurring as an epidemic in childbed, however, it claims separate consideration; but it does not fall within the scope of this work to consider *puerperal peritonitis* fully or separately. It is treated of at length in works on obstetrics and the diseases of women, and to these the reader is referred.

Acute General Peritonitis.

ANATOMICAL CHARACTERS.—The appearances after death, in different periods of the disease, are essentially the same as in other serous inflammations; for example, in pleuritis or pericarditis. Redness, arborescent and punctiform, chiefly from hyperæmia in the subserous areolar tissue, exists, especially if death take place early. The degree of hyperæmia varies much in different cases, and is not to be taken as any criterion of the intensity, or otherwise, of the inflammation. Nor is redness from hyperæmia, be it never so marked, alone adequate proof that inflammation existed. More or less of the inflammatory product, lymph, is always present. The quantity varies much in different cases. It is sometimes abundant, forming a coating more or less thick, extending over the solid and hollow viscera and the parietal portion of the membrane; in other cases, the quantity is moderate or small, adhering to the membrane in patches. It is apt to be most abundant at, and may be limited to, the portions of the intestines which are in contact with each other, frequently agglutinating them together and to the abdominal walls. The

quantity is sometimes slight and spread over the surface in a thin layer so as to escape observation without close attention and scraping the serous surfaces. It is soft and gelatinous if recently exuded, and dense according to its age. The peritoneal sac usually contains effused liquid, the quantity varying much in different cases. The liquid is turbid from lymph, and contains flakes of lymph in more or less abundance. Occasionally it is reddened by the admixture of blood. The serous membrane is more or less opaque and softened. The subserous areolar tissue is morbidly brittle, so that the membrane is more easily detached than in health. In certain cases, and especially if the duration of the disease have been considerable, the peritoneal sac contains pus in more or less quantity. If the peritonitis be connected with perforation of the stomach or intestines, fetid gas escapes on opening the sac, and the contents of these hollow viscera may be found within the serous cavity. Sphacelation of the membrane rarely, if ever, occurs, unless the peritonitis be connected with strangulation or invagination of the intestine. Ulceration from without is extremely rare. Lesions situated in other structures than the peritoneum, and involved in the causation of the peritonitis, are found in a large majority of cases—such as intestinal perforation, invagination, rupture of the urinary or gall-bladder, abscess of the liver or in other situations, etc. etc. Associated lesions are always to be sought for, if not at once apparent. Finally, if life be sufficiently prolonged, morbid adhesions of the intestines to each other, to the solid viscera, and of the opposing parietal and visceral portions of the membrane, are observed. These adhesions are due to the formation of adventitious tissue, as in inflammation of other serous membranes. The adhesions may be more or less extensive. They may consist of bands or bridles of newly-formed membrane, leaving spaces, or loops, in which portions of intestine are liable to become strangulated, thus giving rise to fatal obstruction. The adventitious membranes resulting from inflammation here, as in other serous membranes, are firm and resisting in proportion to their age.

Clinical History.—Acute peritonitis is sometimes developed gradually. Abdominal pain and soreness, progressively increasing, may be felt one, two, or three days before the local and general symptoms are sufficient to show the existence of the disease. But in most cases the attack is abrupt, and the disease quickly declared. Pain is usually a marked symptom. Commencing at a particular point, it extends over the whole abdomen. It is burning or lancinating in character. It is increased at times sufficiently to constitute marked exacerbations, and, not infrequently, in these exacerbations, the character of the pain is that of spasm or colic. Acute pain is produced by a deep inspiration. The respirations are usually shortened, and, by way of compensation, increased in frequency. The movements of the diaphragm are restrained, and those of the ribs proportionately increased; the breathing, in other words, is costal. Acts of coughing and sneezing occasion intense pain. Movements of the body are painful. The degree of suffering from pain varies in different cases. It is generally great, often extreme, occasionally moderate or slight, and this symptom may be wanting. Tenderness on pressure over the abdomen is usually marked. This symptom is very rarely wanting. The tenderness is often such that the slightest pressure is painful, but the degree of tenderness varies considerably in different cases. The pain and tenderness are frequently most marked in a particular circumscribed portion of the abdomen. These symptoms continue during the course of the disease. Owing to these symptoms the patient is apt to lie upon the back

with the knees and thighs raised, in order to lessen the tension of the abdominal muscles and relieve the abdomen of the weight of the bed-clothes. This decubitus, however, is by no means constant. The patient may lie on the side with the knees and thighs flexed, or even on the back with the lower limbs extended. More or less tympanites is generally present. The abdomen is often greatly distended and tense, and this condition persists during the course of the disease. If the tympanites be not great, the abdominal muscles, especially the rectus muscle on either side, is usually notably rigid and resisting. The bowels, as a rule, are constipated, but the exceptions to this rule are not very infrequent. Constipation may exist at first, and subsequently diarrhœa occurs, and occasionally diarrhœa exists at the outset. Vomiting is a frequent and in some cases a prominent symptom. The acts of vomiting occasion great pain. In the latter part of the course of the disease, the contents of the stomach are apt to be ejected by regurgitation rather than by vomiting. Thirst is usually a prominent symptom.

The pulse is more or less accelerated. It is apt to become quite frequent, numbering 120 or 130 per minute; but in some cases the acceleration is moderate. It is generally small and sometimes hard or wiry. The sense of prostration is considerable or great. Perspiration is apt to occur. The countenance denotes gravity of disease; the expression is haggard and anxious. In some cases the upper lip is elevated and drawn tightly over the teeth. This appearance is characteristic, and, when present, points to the disease, but it is by no means uniformly present.

Difficulty in micturition is a frequent symptom, due, probably, in part to paralysis of the muscular tunic of the bladder, and partly to loss of power over the abdominal muscles in consequence of the abdominal distension. Moreover, the pain occasioned by the effort to micturate leads the patient to postpone it as much as possible. Retention of urine, requiring the use of the catheter, is not uncommon. Prof. Rogers, of the University of Louisville, has called attention to the occurrence of severe pain in the penis, in certain cases of peritonitis.[1] This pain is sometimes extremely intense. I have observed this symptom in two cases, since the publication of Professor Rogers' paper, and I have met with several physicians who have observed it. Dr. H. Hunt, of Beloit, Wisconsin, met with an example in a boy six years of age. In some of the cases reported by Prof. Rogers, priapism and intense venereal desire existed. It remains to be ascertained how frequently these symptoms are present. I have ascertained their existence in two cases, since their occurrence was pointed out by Prof. Rogers.

The intellect, in cases of acute peritonitis, is generally not disordered. Slight delirium sometimes occurs, especially in fatal cases, toward the close of the disease.

Pathological Character.—Acute peritonitis, as regards pathological character, does not differ essentially from other acute, serous inflammations.

Causation.—Acute inflammation of the peritoneum, exclusive of puerperal peritonitis, is rare. As a spontaneous or idiopathic affection, it is one of the rarest of diseases. The liability of the peritoneum to become inflamed is vastly less than of the pleura or the pericardium, a fact not easily explained, but which exemplifies a principle of conservatism, inas-

[1] Western Journal of Medicine and Surgery, Louisville, Aug., 1855, vol. iv. No. 2.

much as peritonitis is a much more serious disease than either pleuritis or pericarditis. In the great majority of cases, peritonitis is incidental to some other affection of the abdominal viscera. The most frequent cause, exclusive of its occurrence in childhood, is perforation of the alimentary canal. Perforation of the ileum is incidental to the intestinal lesions of typhoid fever, and peritonitis thus produced is one of the occasional events pertaining to the clinical history of that form of fever. The intestinal ulcerations which occur in certain cases of tuberculosis, sometimes, although very rarely, lead to perforation, and, also, other ulcers situated in either the small or large intestine. Perforation from ulceration or sphacelation of the extremity of the appendix vermiformis of the cæcum is not of very rare occurrence; several examples have fallen under my observation. Perforation of the stomach is an occasional event in cases of gastric ulcer. Whatever be the seat of the perforation, the gaseous and other contents of the alimentary canal escaping into the peritoneal sac, peritonitis becomes at once developed. The escape of bile from rupture of the gall-bladder, or of the cystic, hepatic, or common duct, gives rise to peritonitis. Other causes are the discharge of pus into the peritoneal cavity from hepatic, ovarian, or other abscesses, rupture of the urinary bladder or ureter, and the evacuation of hydatid cysts. Inflammation, at first local, may become general, as in certain cases of invagination and strangulation of intestine. Injections into the cavity of the uterus have been known to give rise to the disease, the liquid injected passing into the peritoneal cavity through the Fallopian tubes. In certain cases of puerperal peritonitis, the inflammation commences in the uterus and is propagated to the peritoneum. The disease may be produced traumatically by wounds of the abdominal walls, and violent contusions. It follows sometimes paracentesis, very rarely, however, except in cases in which the kidneys are diseased.

Excluding cases of acute peritonitis produced by these various causes, together with all cases of puerperal peritonitis, the remaining cases which occur are exceedingly few. Of the few which remain, probably in most the disease is developed in connection with renal disease. Acute peritonitis is one of the local affections incidental to the morbid conditions of the kidneys collectively called Bright's disease. In a case under my observation at Bellevue Hospital, it was developed in connection with acute articular rheumatism, the patient recovering after a short duration of the disease. Exposure to cold may give rise to it. I have known its occurrence to be fairly attributable to this cause. The late Prof. Palmer, of Louisville, informed me that in the neighborhood of Woodstock, Vermont, where he formerly resided, cases of acute peritonitis were not very uncommon among persons employed in the winter and spring to repair water-wheels damaged by ice, this occupation requiring them to work standing in water.

Occurring as an epidemic affection, in childbed, it doubtless proceeds from a special cause. During the prevalence of puerperal peritonitis, epidemic erysipelas has been observed to prevail, showing some pathological relationship between the two affections.

In autopsical examinations, the various local causes of peritonitis are to be sought for. Without care they may be overlooked. A small intestinal perforation will be likely to escape detection unless careful search be made, and is probably not infrequently overlooked.[1]

[1] For an analysis of 500 cases of peritonitis with reference to etiology and treatment, by Dr. Samuel O. Habershon, *vide* Medico-Chirurgical Transactions, pub-

Diagnosis.—The diagnosis of acute peritonitis is not difficult in cases in which its diagnostic features are well marked, as they are in the majority of cases. These features are sometimes obscure or wanting, and it is then liable to be overlooked or confounded with other affections. From acute enteritis it is distinguished, generally, by a greater degree of pain, greater frequency of the pulse, more tenderness on pressure over the abdomen, more tympanites, rigidity of the abdominal muscles, absence of diarrhœa, and the evidence, on all sides, of a graver malady. Rare as is acute peritonitis, acute enteritis, at least in the adult, is still more infrequent.

It is sometimes mistaken for functional colic. The pains, in some cases of peritonitis, are like those of colic. But colic lacks the continuous pain, the abdominal tenderness, the muscular rigidity, the tympanites, the frequency of the pulse, prostration, etc., of acute peritonitis. These symptoms, however, may not be immediately developed in peritonitis, and a little delay may, therefore, sometimes be necessary in arriving at a positive diagnosis.

Rheumatism, affecting the abdominal muscles, may give rise to certain of the local symptoms of acute peritonitis. Instances, however, of rheumatism limited to these muscles must be extremely rare. The diagnostic points, indicated by Genest, are as follows:[1] In peritonitis, movements of the body occasion pain over the whole abdomen, whereas, in rheumatism, the pain is apt to be limited to certain muscles, and, perhaps, confined to one side of the abdomen. The same is true of tenderness on pressure. Moreover, in peritonitis the pain from pressure is proportionable to its amount, but in rheumatism, deep, firm pressure may be made without augmenting the pain.

Lumbo-abdominal neuralgia, with hyperæsthesia of the abdominal walls or integument, sometimes simulates closely peritonitis as regards certain local symptoms. The pain may be severe, the tenderness great, the decubitus on the back with the thighs and knees flexed and, not infrequently, there is more or less tympanites. Cases presenting these symptoms are not uncommon. The patients are generally females, and manifest more or less of hysterical phenomena. The general symptoms of acute peritonitis, frequency of pulse, prostration, etc., are wanting in these cases; but attention to certain points connected with the local symptoms will suffice for the differential diagnosis. The tenderness in the neuropathic affection is more superficial; the patient shrinks from the slightest touch, but firm, prolonged pressure with the open palm is often well borne, and may even afford relief, whereas, in peritonitis, the pain is always proportionate to the amount of pressure. The muscular rigidity of peritonitis is wanting. It is stated by Valleix that tenderness in these cases exists by the side of the vertebral column, and that the tenderness in front is especially marked at a point situated at or a little above the middle of the crest of the ilium.

I have known acute peritonitis to be mistaken for sporadic cholera in a case in which vomiting and purging occurred early, and were prominent

lished by the Royal Medical and Chirurgical Society of London, vol xliii. 1860. From an analysis of these cases Dr. H. draws the following conclusions: Peritonitis is never idiopathic in its origin, but, when not traumatic nor due to perforation of viscera, it is dependent on either an extension of disease from adjoining viscera; or on certain blood changes, such as occur in albuminuria, pyæmia, etc.; or on certain nutritive changes of the system connected with struma, cancer, etc.; or, lastly, on local hyperæmia arising from cirrhosis, disease of the heart, etc.

[1] Valleix, *op. cit.*

symptoms. In the exceptional cases in which these symptoms are sufficiently prominent to suggest that affection, the error of diagnosis is to be avoided by finding, associated with the vomiting and purging, the local symptoms of peritonitis, viz., pain, tenderness, tympanites, and muscular rigidity, together with general symptoms denoting an inflammatory affection, symptoms not belonging to the history of sporadic cholera.

Acute peritonitis is sometimes remarkably latent, the local symptoms, usually so strongly marked, being obscure or wanting. Pain and tenderness may be slight or even absent; tympanites is not always present. Muscular rigidity in such cases may be a very valuable diagnostic symptom. As regards occasional latency, this disease resembles other serous inflammations, viz., pleuritis and pericarditis. Pain and tenderness may be obscure in consequence of the coexistence of other affections which occasion delirium or blunt the perceptions of the patient, and from the absence of these local symptoms, peritonitis may be overlooked. In some cases of peritonitis produced by perforation, in the course of typhoid fever, for example, the manifestations of pain and tenderness may not be sufficient to direct attention to the abdomen. In such cases, other local, in conjunction with general, symptoms must be relied upon in the diagnosis.

It is desirable, in cases of peritonitis, to determine whether the disease be idiopathic or dependent on some one of the various local circumstances which stand in a causative relation to it in the majority of cases. In consequence of the relative infrequency of idiopathic peritonitis, the probabilities, in any case, are in favor of the existence of some one of these causative circumstances. Developed in the course of typhoid fever, it generally, but not invariably, proceeds from perforation of the ileum. If developed in a case of pulmonary tuberculosis accompanied by diarrhœa, chronic peritonitis not preceding its development, perforation, connected with intestinal ulceration, is the probable cause. Perforation of the stomach is probable if the peritonitis occur suddenly in a case presenting the symptoms of gastric ulcer. Perforation of intestine, connected with latent ulceration, is to be very strongly suspected whenever the affection is developed suddenly, without any appreciable cause, in a person apparently in health; and if the pain and tenderness first occur in the neighborhood of the cæcum, and continue most marked in this region, the seat of the perforation is probably the appendix vermiformis. The points just stated, however, do not positively denote perforation of intestine. For example, they were present in a case recently under my observation, in which the peritonitis was due to perforation from ulceration of the gall-bladder. Perforation of the ureter may be strongly suspected if the sudden development of the disease have been preceded by symptoms denoting obstruction from calculus or some other cause. In like manner, perforation of the ductus communis choledochus is the probable cause if symptoms denoting the impaction of a gall-stone in this duct have preceded. The disease is attributable to invagination or internal strangulation of the intestine when preceded and accompanied by symptoms denoting these causes of obstruction of the bowels. Its connection with renal disease is to be determined by an examination of the urine for albumen and casts from the uriniferous tubes. Finally, if evidence of the existence of any of the causative circumstances referred to be wanting, and the disease be fairly attributable to exposure to cold, it may be considered as idiopathic.

Prognosis.—Acute general peritonitis is always a grave disease, involving more or less danger to life. In the majority of cases, the danger is greatly enhanced, either by the circumstances on which the development

of the disease depends, for example, intestinal perforation, or by coexisting affections, for example, renal disease. We have no data for determining the amount of intrinsic tendency to death belonging to simple idiopathic peritonitis. There is reason to believe that the rate of fatality in all cases depends very much on the mode of management. Judiciously treated, in uncomplicated cases, the prospect of recovery is good. In complicated cases, including under this head cases in which the disease is connected with gastric or intestinal ulceration, Bright's disease, etc., the prognosis must always be very unfavorable. Under certain circumstances, the disease runs rapidly to a fatal issue. It may destroy life within a few hours, developed as a result of perforation. Recovery, however, is not impossible in cases of perforation, provided the opening be not large and closure be quickly effected by adhesions around it. The average duration in fatal cases is from five to six days.

The mode of dying is by either rapid or slow asthenia. An unfavorable progress of the disease is denoted by a progressive increase of the feebleness and frequency of the pulse, progressively increasing prostration, coldness of the extremities, hiccough, regurgitation, etc. On the other hand, a favorable progress may be predicated upon improvement as regards the general symptoms just referred to, together with diminution of the tympanites and muscular rigidity of the abdomen. Convalescence is apt to be slow, more or less tenderness and colic pains persisting during the progress toward recovery.

Treatment.—Within a few years, an important change of practice, as regards the treatment of acute peritonitis, has taken place in this city (New York), and, to a considerable extent, throughout the country. There are grounds for the belief that, by means of the method of treatment which will be here recommended, this disease is managed much more successfully than heretofore. The change consists, *first*, in the disuse of bloodletting and cathartics; and, *second*, in relying mainly on the use of opium. Governed by the general principles which should regulate the employment of bloodletting in acute inflammations, the indications for this measure are very rarely, if ever, present in peritonitis, a disease which tends to destroy life, and sometimes very quickly, by asthenia. Having considered these general principles, I do not deem it necessary to enter into a consideration of the reasons for the opinion that, as a rule to which there are few, if any, exceptions, bloodletting, either general or local, is contra-indicated in the treatment of acute peritonitis. Bloodletting has been much employed in the treatment of this disease, and certainly, clinical observation has abundantly shown that it is not, to say the least, a curative measure. It is a measure which in this, as in other diseases, must do either good or harm; and in a disease, like this, involving always not a little danger to life, if it do harm instead of good, the amount of harm, even if not large, may bear heavily on the result. Cathartics, also, have been much employed in the treatment of this disease. Not only are they devoid of curative efficacy, but they are highly pernicious. An important point in the treatment of an acute inflammation of any part, is to secure for the part as much rest as possible. The friction incident to the peristaltic movements tends to perpetuate and intensify the inflammation in peritonitis. It is an object of treatment to arrest these movements, and thus secure rest for the inflamed membrane. Cathartics not only conflict with the means for effecting this object, but they aggravate the inflammation by increasing the peristaltic movements. Moreover, they are objectionable on the same score as bloodletting and other depletory and depressing measures. Clin-

ical observation certainly furnishes no evidence of the usefulness of cathartics in the treatment of acute peritonitis. On the other hand, it has occurred to me, as to others, to see the intensity of the inflammation reproduced by the too early administration of a cathartic, when the disease appeared to be progressing favorably, and the patient's life apparently lost in consequence. Cathartics, then, should not enter into the treatment of this disease. The bowels should be allowed to remain constipated, if evacuations do not spontaneously occur, during the career of the disease, even if this period be a week or more. In pursuing this course, the physician must expect, in some cases, to encounter the importunities of the patient or friends for medicine to open the bowels. If the patient suffer from an accumulation of feces within the rectum, its contents may be cautiously removed by repeated simple injections.

The use of opiates in the treatment of acute peritonitis is not of very recent date. Armstrong, more than a quarter of a century ago, advocated full doses of opium in conjunction with bleeding and mercury, attaching the greater relative importance to the opium. Watson, in his admirable *Lectures on the Principles and Practice of Physic*, the first edition published more than 25 years ago, considers opium as of great value, and points out the evils of cathartics. This author refers to cases reported by a British physician, Bates, in which opium and rest were relied upon mainly in the treatment. More especially Graves, and afterward Stokes, of Dublin, called the attention of the profession to the subject, by reporting cases in which the disease was successfully treated with the free use of opium. They advocated the importance of this mode of treatment more particularly in cases of peritonitis due to perforation. But the credit of inaugurating the treatment of acute peritonitis by opiates exclusively is, in a great measure, due to Prof. Alonzo Clark. Moreover, to Prof. Clark is due the credit of ascertaining that, in certain cases of peritonitis, there is a remarkable tolerance of opiates, and that, to secure their curative power, it is sometimes necessary to employ them in enormous doses. The attention of the profession of this country was first called to the efficacy of this plan of treatment, by the publication of cases of puerperal peritonitis treated by Prof. Clark, in the lying-in wards of Bellevue Hospital, in 1851–52. Prof C., however, was led to apply this method of treatment to these cases from his previous experience of its efficacy in simple peritonitis.

An important object effected by opiates is the arrest or retardation of the peristaltic movements; this is a special object in this disease, but opiates are useful in this, as in other inflammations, by rendering the system more tolerant of the local affection. The latter is also an object to be effected. With reference to both these objects, opiates are to be given in doses sufficient to produce certain effects. Relief of abdominal pain is generally evidence that the first object is effected. The doses, therefore, should be sufficient to produce this effect. The pain is to be relieved as quickly as possible, and the return of pain prevented by repeating the required doses at short intervals. Diminished frequency of the pulse is the best criterion of the desired effect upon the system. The success of the treatment will depend much on its being commenced early in the disease. Time should not be wasted by delay for any preliminary measures. A full dose should commence the treatment, the amount being regulated by the intensity of the pain. For an adult, from half a grain to a grain of a salt of morphia, or an equivalent dose of some other form of opiate, may be given at once. In two or three hours the effects of the first dose can be appreciated. If the patient be not then free from pain,

another dose is to be given, the amount of this dose being determined by the degree of pain. And, during the course of the disease, the opiate is to be repeated, if required, at intervals of from two to three hours, in doses sufficient to prevent return of pain. Undue narcotism is, of course, to be avoided. In order to avoid this, the physician is to observe the effects as regard somnolency, contraction of the pupil, and diminished number of respiration. It is never necessary to produce a degree of narcotism involving any danger. Judgment and careful watching, however, are important, lest an unnecessary degree of narcotism be produced. The somnolency from the opiates should never become so great that the patient cannot be easily aroused. The respirations should not remain below ten or twelve per minute. If, as not infrequently happens, they are found below this number, or irregular, the intervals between the doses are to be lengthened or the doses diminished. In carrying out this method of treatment, it is desirable that the physician should see the patient frequently. If this be impracticable, as it often will be in country practice, the administration of the doses must be intrusted, with minute instructions, to an intelligent and faithful assistant or nurse. The doses are to be gradually diminished in proportion as the local and general symptoms denote improvement, and, at length, discontinued.

The extent to which opiates are to be given in order to secure the objects of the treatment will vary much in different cases. Other things being equal, the doses required will depend on the degree of pain. But the susceptibility of different persons to opium varies greatly, and in peritonitis, as in some other diseases, there is sometimes an extraordinary tolerance of this remedy. Thus, in one of the cases treated successfully by Prof. Clark, the patient took within the first 26 hours, of opium and the sulphate of morphia, a quantity equivalent to 106 grains of opium; in the second 24 hours, she took 472 grains; on the third day, 236 grains; on the fourth day, 120 grains; on the fifth day, 54 grains; on the sixth day, 22 grains; on the seventh day, 8 grains, after which the treatment was suspended. This patient Prof. C. had reason to believe was not accustomed to the use of opium in health, and was not intemperate. As regards the amount of opium required, this case is exceptional. Generally, according to Prof. C., in private practice, not more than half or two-thirds of a grain of a salt of morphia every two hours is needed. This accords with my experience. Often the requisite effects are produced with doses much less than those just named. The manner of conducting the opiate treatment may be illustrated by a tabular statement of the doses and symptoms at intervals of from two to three hours, in a case in my service at Bellevue Hospital, the treatment being carried out by the senior assistant.[1] In this case, death took place on the tenth day, from the development of dysentery, the symptoms, as regards the peritonitis, denoting convalescence at the time the dysenteric affection became developed. The autopsy showed that the peritonitis was due to perforation of the gall-bladder from an abscess between its coats. The parts were agglutinated with recent lymph at the perforation, and the appearances of the peritoneum were consistent with convalescence from the peritonitis. Although fatal from an intercurrent disease, this case exemplified the utility of the opiate treatment, and the autopsy leaves no room for distrust of the diagnosis.

The patient, a tailor, aged 30, was suddenly attacked with sharp ab-

[1] By Dr. George Engs. This case was reported by Dr. Engs in the American Medical Times, Jan. 9, 1864.

dominal pain the day but one before his admission, and had had no treatment prior to entering the hospital. He was placed at once on the opiate treatment, and the following table, prepared by Dr. Engs, gives the doses, pulse, and respirations, with remarks, at intervals of from two to three hours :—

Time.	Pulse.	Resp.	Magendie's Solution Morph.	Remarks.
Nov. 27th, 1¾ P. M.	120	36	gtt. xv.	
" 5 "	128	36	" xv.	Complains of nausea.
" 7¾ "	108	28	" x.	No pain except on motion.
" 12 M.	108	20	" xx.	Restless.
Nov. 28th 2 A. M.	108	17	" xv.	Has vomited.
" 6 "	100	11	" x.	Dozing.
" 9 "	102	10	" x.	
" 11¼ "	106	12	" v.	No pain.
" 1¾ P. M.	102	12	" v.	
" 4¼ "	104	10	" 0.	No pain.
" 6 "	100	11	" 0.	Vomiting repeated.
" 9 "	92	9	" 0.	Asleep.
" 11½ "	108	18	" v.	Restless.
Nov. 29th, 3½ A. M.	108	25	" xv.	Restless; thin yellowish stool.
" 8 "	100	13	" v.	
" 10 "	88	9	" 0.	Rigidity of abdomen much
" 1 P. M.	90	13	" iv.	diminished.
" 4 "	90	13	" v.	
" 7¾ "	106	14	" vi.	Bowels again moved.

Dysenteric dejections occurred on the 30th instant, and death took place in six days afterward, the abdominal tenderness, rigidity, and tympanites having mostly disappeared.

In the treatment of this disease the main reliance is upon opiates. But other measures are important. Quietude of the body is to be enjoined; the bladder is to be relieved by the timely use of the catheter, if there be retention of urine. Rubefacients, sinapisms, or turpentine stupes may be applied over the abdomen; blisters are contra-indicated. All the good to be done in the way of revulsion will be effected by rubefacients, and counter-irritation beyond this does harm by increasing constitutional disturbance and contributing to depress the powers of life. Warm fomentations to the abdomen, if grateful to the patient, are useful; poultices are uncomfortable from their weight; the water-dressing or the spongio-piline is to be preferred. Cold applications are recommended, after trial, by Grisolle and Allison. I cannot speak of their utility from observation, but I should be willing to trust to the feelings of the patient in deciding between cold or warm applications. Cold applications, provided they are well borne by the patient, are recommended by Niemeyer, employed in the same way as in acute pleuritis, namely, by means of compresses dipped in cold water and renewed every ten minutes. Sustaining measures are indicated in proportion as the symptoms denote failure of the vital powers. Tonics, alcoholic stimulants, and concentrated nourishment constitute the supporting measures, not less appropriate to this than to other diseases which tend to destroy life by asthenia. I have seen the life of a patient apparently saved by the free and persevering use of alcoholic stimulants, in conjunction with the use of opiates. The employment of cathartics in convalescence calls for great circumspection; they may not be required, the bowels acting spontaneously. The free use of opiates continued throughout the

disease does not appear to conduce to constipation, and does not prevent the occurrence of diarrhœa in a certain proportion of cases.

The employment of mercury claims a few remarks. Mercurialization has been deemed highly important in this disease by most practitioners heretofore, and it is still deemed important by many. It is supposed to be useful in this, as in other serous inflammations, by limiting exudation and promoting its absorption. The opinion has already been expressed that the so-called antiplastic and sorbefacient action of mercury has been much exaggerated, but that we are not authorized with our present knowledge to deny to this remedy any curative power. And it is perhaps questionable whether, in so grave an affection as acute peritonitis, we are fully warranted in omitting this remedy. I must confess, however, that for some years past it has not entered into the treatment of the cases of which I have had charge. The employment of mercury should not diminish the reliance on opiates; and it should be so employed as not to interfere with the objects of the opiate plan of treatment. If given internally, it should be in fractional doses, so as to avoid a cathartic effect, but a preferable mode is its employment by inunction.

In endeavoring to determine clinically the relative value of different methods of treatment, cases should be grouped according to the different circumstances giving rise to the peritonitis. As regards the prospect of success from any treatment, cases of perforation, evacuation of pus into the peritoneal cavity, rupture of the gall-bladder, etc., are not to be classed with cases of simple peritonitis. Moreover, the disease, more especially in its simple form, is too rare for a clinical observer, however large his field of practice, to accumulate many cases. I have notes of thirty-five cases which have fallen under my own observation. Of these thirty-five cases, seventeen proved fatal, death being attributable to the peritonitis *per se*. In addition to these seventeen fatal cases, death was attributable in one case to dysentery which was developed during apparent convalescence; in one case the peritonitis supervened on acute pleurisy, the patient dying as if by "shock," and in one case death took place after the patient had recovered from the peritonitis sufficiently to be up and about, the immediate cause of death not having been ascertained. Adding these three cases and the whole number of those ending fatally is twenty. Of the fatal cases, exclusive of the three cases just referred to, the autopsy showed in four rupture of the vermiform appendix of the cæcum, in one case fracture of the liver from injury, in two cases suppuration of the ovaries, in both an abscess having opened into the peritoneal cavity; and in one case there was rupture of intestine from violent efforts made by the patient in reducing a hernia. In three cases there was no apparent local cause of this peritonitis. In six cases there was no autopsy. Of the three cases of simple peritonitis (as determined by the autopsy), and only those proving fatal, the opiate treatment was commenced in one case on the third day; in one case a cathartic was given on the third day and the patient was not kept quiet, and in the remaining case the opiate treatment was imperfectly carried out. Of the six fatal cases in which no autopsy was made, three were treated with cathartics and bleeding. In two cases the opiate plan was moderately carried out, and in one of these cases the patient was considered as convalescent, and allowed to sit up, when a renewal of the symptoms took place, followed by speedy death. In the remaining case the opiate treatment was efficiently carried out until the patient appeared to be nearly convalescing, when, yielding to the importunities of friends, a cathartic was given, after which the intensity of the disease was reproduced,

and the case speedily ended fatally. Of the fifteen cases ending in recovery the treatment was exclusively or chiefly by opium.

These analytical results are submitted as affording evidence of the efficacy of the method of treatment by opium after the plan pursued by Prof. Clark.

Partial or Circumscribed Peritonitis.

Inflammation limited to a circumscribed portion of the peritoneum is almost invariably a complication of a prior affection of the parts covered by the inflamed portion of the membrane. In this respect the same law holds good with reference to the pleura and peritoneum. Ulceration of the stomach, for example, leads to a peritonitis limited to the site of the ulcer, and the contiguous parts become adherent at that point—a conservative provision against perforation. Inflammation of the uterus extends to the portion of this membrane covering that organ. Affections of the liver sometimes lead to inflammation of the peritoneal investment of this viscus (*peri-hepatitis*). In consequence of this partial peritonitis, the liver sometimes becomes covered with lymph, and closely adherent to the adjacent parts; hence one source of atrophy with diminished volume of the liver, and consequent dropsy of the peritoneum. In like manner, partial peritonitis may be limited respectively to portions of membrane in relation with the spleen, the pancreas, the ovaries, etc. A small perforation of the intestinal canal may give rise to only partial peritonitis, the orifice becoming closed by exudation of lymph and adhesions.

The diagnosis of partial peritonitis is to be based upon circumscribed pain and tenderness, with perhaps more or less febrile movement. These symptoms are marked in proportion to the acuteness of the inflammation; but partial peritonitis is oftener subacute than acute. Physical exploration, in some cases, furnishes diagnostic evidence. The presence of lymph may occasion a friction sound or a tactile sensation of rubbing due to the attrition of opposed surfaces with the diaphragmatic respiratory movements. It is most apt to be obtained when the peritonitis is situated over the liver and spleen. It is obtained in cases of partial oftener than of general peritonitis, and is of comparatively less importance in the latter, because the symptoms generally suffice for the diagnosis of general peritonitis.

It must be difficult, if not impossible, to determine the existence of partial peritonitis not connected with an affection of the parts covered by the inflamed portion of peritoneum. Cases, however, are so rare that, the existence of partial peritonitis being ascertained, a complicating affection of the parts covered by the inflamed portion is to be inferred.

The prognosis in cases of partial peritonitis will depend on the nature and extent of the affection of which the peritonitis is a complication. The adhesions resulting from the inflammation, as has been seen, may be either conservative or deleterious.

So far as the peritonitis is concerned, palliative treatment is alone called for.

Chronic Peritonitis.

Exclusive of partial peritonitis, inflammation of the peritoneum is oftener acute than chronic. Cases of idiopathic, chronic, general peritonitis certainly belong among the curiosities of medical experience. In cases of chronic peritonitis, the inflammation is generally either consecutive to a prior affection of the abdominal viscera, or it is secondary to an

affection situated elsewhere. Occasionally acute pertionitis eventuates in the chronic form of the disease. This is rare. In cases of acute peritonitis, if life be not destroyed by the acute disease, recovery, as a rule, takes place. The patient is liable to suffer for some time from weakness or disorder of the intestinal canal, and adventitious membranes resulting from the disease may occasion inconvenience; but the inflammation does not persist, save in exceptional cases.

Of cases of chronic, not succeeding acute, peritonitis, in the great majority the affection is developed in connection with the tuberculous cachexia. The affection is then commonly known as *tuberculous peritonitis*. Post-mortem examination, in these cases, generally reveals, in addition to appearances denoting peritoneal inflammation, either the yellow tubercle associated frequently with tuberculosis of the mesenteric and intestinal mucous glands, or the gray semi-transparent granulations. The latter, according to Robin, are produced consecutively to the peritonitis. Tuberculous products within the abdomen, however, are not invariably present in cases of peritonitis developed in connection with the tuberculous cachexia. The observations of Louis show that tuberculous patients are liable to chronic peritonitis irrespective of the presence of tubercle either beneath or upon the peritoneum, and irrespective of a tuberculous or other affection of any of the abdominal viscera, the peritonitis, in these cases, being attributable to the tuberculous cachexia. So generally is chronic peritonitis associated with the tuberculous cachexia, that, the existence of the former being ascertained, the latter may be inferred, provided the peritonitis be general, not traumatic, and acute peritonitis have not preceded. Moreover, since, after childhood, the local manifestations of the tuberculous cachexia almost invariably first take place in the lungs, pulmonary tuberculosis may be inferred with much positiveness from the existence of chronic peritonitis, with the qualifications just stated. For our knowledge of these relations of chronic peritonitis, we are mainly indebted to the clinical researches of Louis.[1]

In a certain proportion of cases, chronic peritonitis occurs in connection with carcinoma either seated in the peritoneum, or originating in other structures and extending to this membrane. The inflammation, in these cases, is excited by the carcinomatous disease. The affection, in these cases, may be called *cancerous peritonitis*.

After death, in cases of chronic peritonitis, more or less liquid effusion is frequently found in the peritoneal sac. The quantity, as a rule, is not large; not infrequently it is small, and in some cases there is no accumulation. An effusion frequently takes place in considerable quantity, which either diminishes or disappears before death. Exceptionally, the amount of effusion is so great that paracentesis is required. I have known this to occur in cases of cancerous peritonitis. The effused liquid contains lymph in more or less abundance. Merely serous effusion, here as elsewhere, is no evidence of inflammation. The peritoneal cavity may contain pus in greater or less quantity. A purulent collection here sometimes leads to ulceration and perforation of the intestine or of the abdominal walls, as in empyema the pus makes its way into the bronchial tubes or through the parietes of the chest. The intestines are agglutinated to each other, the solid viscera, and the abdominal walls by means of lymph, and permanent adhesions follow. The latter alone are evidence, not of existing but of past inflammation. If the disease have been of considerable or long duration, the intestinal convolutions are sometimes bound together,

[1] Recherches sur la Phthisie.

or connected with the solid viscera, so as to form masses of considerable size, which are appreciable, by palpation, through the abdominal walls.

As regards the clinical history and diagnosis, chronic peritonitis is frequently obscure, belonging among the affections called insidious, and its existence is not always readily determined. If it follow acute peritonitis, it is less likely to escape detection than when it is subacute from the beginning. Under these circumstances, the persistence of pain and tenderness, the presence of liquid effusion in greater or less quantity, continued rigidity of the abdominal muscles, together with general debility, emaciation, in some cases febrile movement, etc., render the diagnosis sufficiently clear.

Tuberculous peritonitis is, from the first, subacute. The researches of Louis show the symptoms to be as follows: Augmentation of the size of the abdomen from tympanites and liquid effusion, the latter denoted by fluctuation; abdominal pains, often not marked, with tenderness on pressure; diminution of the enlargement from liquid effusion and perhaps disappearance of the sense of fluctuation after a time; the tympanites in some cases diminishing after a time, and followed by tension of the abdominal walls; the intestinal convolutions sometimes, after the tympanites has disappeared, apparent through the walls of the abdomen. Pains and tenderness are sometimes wanting, the patient making no complaint of the abdomen, and rough pressure being well borne. In some cases the abdomen has to the touch a doughy or boggy feel. Peritoneal friction is sometimes heard or felt. With these local symptoms are associated more or less acceleration of pulse, perspiration during sleep, hectic paroxysms, progressive emaciation, anæmia, general debility, etc. After childhood, pulmonary tuberculosis will be found to exist in a vast majority of cases. With the foregoing local symptoms, especially if tuberculous enteritis be excluded by the absence of diarrhœa, the existence of pulmonary tuberculosis tends to strengthen the diagnosis of chronic peritonitis. The tuberculous affection of the lungs in some cases is quite latent as regards pulmonary symptoms, and its existence is to be determined by means of physical signs.

In cancerous peritonitis, the local symptoms do not differ materially from those in tuberculous peritonitis. Febrile movement is less constant and marked in the former; perspiration is not so apt to occur. The age of patients is greater than in the majority of cases of the latter. The cancerous affection within the abdomen may be secondary to cancer in other situations open to examination. Pulmonary tuberculosis does not coexist.

The prognosis in all cases is unfavorable. A fatal termination, sooner or later, even if the peritonitis be not connected with either tubercle or cancer, is the rule. The duration of the disease in these cases may be long. I have met with a case in which the history appeared to show that the affection had existed for a great number of years before death. Tuberculous and cancerous peritonitis are always fatal, the duration varying from one or two months to a year or more. The fatal termination is hastened by coexisting pulmonary disease, in cases of tuberculous peritonitis, and frequently by tuberculous enteritis and other local affections.

From what has just been stated with reference to the prognosis, it follows that chronic peritonitis is not to be treated with an expectation of recovery. If the peritonitis be simple, the indications are to palliate the local symptoms, and, by the use of tonic remedies, nutritious diet, and other hygienic measures, to strengthen the system and enable it to endure the local affection as long as possible.

Considerable may be done in this way to prolong life, and this conservative plan of treatment will be most likely to effect a cure if recovery be possible. Cathartics, mercurialization, local depletion, and all depressing remedies are contra-indicated. In cases of tuberculous peritonitis, the treatment embraces the measures, in addition to those just named, which have reference to the tuberculous cachexia, viz., cod-liver oil and alcoholic stimulants, provided these are well borne. Cancerous peritonitis claims essentially the same treatment. The local palliative treatment embraces opium, according to the degree of pain, soothing and moderately stimulating liniments applied to the abdomen, protection of the abdomen against cold by the application of plasters and flannel, and mechanical support with moderate compression of the abdomen.

Occasionally, in cases of chronic peritonitis, the accumulation of liquid in the peritoneal sac is sufficient to occasion inconvenience and even danger by compressing the abdominal viscera and interfering with the play of the diaphragm. Under these circumstances are indicated measures to effect the diminution or removal of the liquid. These measures, including paracentesis, will be considered in treating of dropsy of the peritoneum.

Peritonitis is sometimes developed in newly-born children, and during intra-uterine life.

Hydro-Peritoneum.

The term hydro-peritoneum denotes peritoneal dropsy. The term *ascites* is commonly applied to cases of dropsy of the peritoneum, and also to cases in which liquid effusion is a result of peritonitis. In a pathological view, a dropsical differs essentially from an inflammatory effusion, and the distinction is of practical importance. The accumulation of liquid from inflammation has been noticed in treating of peritonitis. Under the present head, reference is had exclusively to cases of dropsical effusion, the effused liquid being purely a transudation, *i. e.*, not containing lymph, and the peritoneum free from inflammation. Like other dropsies, hydro-peritoneum is a symptom or an effect of disease, not strictly a disease *per se*. But the accumulation of liquid may be the first and chief manifestation of disease; it occasions inconvenience and danger, and therapeutical measures are especially directed to it. Moreover, it is not practicable in all cases to trace the dropsy to its causative morbid condition. Hence the convenience and propriety of considering it as an individual disease. Peritoneal dropsy occurs in conjunction with dropsical effusion into the pleural sac, and the areolar tissue throughout the body, or anasarca. Hydro-peritoneum is, however, to be considered as an individual affection only when it occurs as a local dropsy, *i. e.*, not as an element of general dropsy.

In the great majority of cases, hydro-peritoneum, occurring as a local dropsy, proceeds from morbid conditions seated in the liver. And, of these, the structural affection known as *cirrhosis* especially gives rise to peritoneal dropsy. This affection will be considered in connection with the diseases of the liver. Atrophy of the liver from compression by lymph upon its surface and morbid adhesions to surrounding parts leads to this form of dropsy. The dropsy in these cases is due to obstruction to the passage of blood through the liver, the transudation into the peritoneal sac being an effect of the hydraulic pressure upon the coats of the portal veins, caused by the hepatic obstruction. In so large a proportion of cases is hydro-peritoneum dependent on disease of the liver, that the

latter is always presumable, assuming that general dropsy does not exist. It is generally considered that enlargement of the spleen may give rise to hydro-peritoneum. There is little or no foundation for this opinion. Enlargement of the spleen occurs in a small proportion of cases of dropsy dependent on cirrhosis of the liver, and occurring without the latter affection, as, for example, a sequel of intermittent fever, it is not accompanied by peritoneal dropsy. Obstruction of the *vena portæ* by the pressure of a tumor, by the presence of a thrombus, or as a result of adhesive phlebitis, gives rise to peritoneal dropsy in the same way as obstruction due to hepatic lesions, viz., transudation taking place from hydraulic pressure. According to Frerichs, coagula in the portal vein take place, without inflammation, in consequence of weakened force of the circulation, from compression, exterior to the liver, by swellings or tumors, and in connection with various hepatic affections.[1] Cardiac and renal disease do not give rise to peritoneal, save as an element of general, dropsy. Clinical observation shows, in a small proportion only of cases of hydro-peritoneum occurring as a local affection, evidence of disease, either of the heart or kidneys.[2] In the vast majority of cases, the dropsy is dependent on structural lesions of some kind; that is, it occurs very rarely as a functional affection. Of forty-six cases coming under my observation, which I have analyzed, in one case only was the history consistent with the supposition that the affection was purely functional.

Various causes may co-operate with the morbid conditions upon which peritoneal dropsy is dependent. Diseases of the heart, renal disease, anæmia resulting from intermittent fever, lactation, etc., may be mentioned as co-operating causes. It may be doubted, however, if these causes alone ever give rise to the affection. Indirectly they favor its occurrence and determine the epoch when the dropsical effusion takes place.

The effusion of liquid and its accumulation take place usually without pain, tenderness, or any local subjective symptoms. The enlargement first directs attention to the abdomen. In the majority of cases, when this begins it goes on with rapidity, and the abdomen soon becomes considerably or greatly distended. The symptoms referable directly to the dropsy proceed from the mechanical pressure of the liquid, and, other things being equal, are in proportion to the quantity of effusion. The distension of the abdominal walls by the liquid, and its weight, occasion more or less inconvenience. The functions of the abdominal organs—stomach, liver, kidneys—are impaired by compression. Pressure on the veins within the abdomen gives rise to, or increases, œdema in the lower extremities. The movements of the diaphragm are restrained or arrested, breathing being carried on by the costal muscles, and, if the accumulation be very large, the capacity of the chest is diminished by the upward pressure, and the embarrassment of respiration may be sufficient to destroy life. The appetite is usually more or less impaired. A sense of fulness is frequently felt after taking food in moderate quantity. Vomiting and diarrhœa are occasional symptoms. Hæmatemesis occurs in a certain proportion of cases.

Enlargement of the superficial veins on the anterior aspect of the trunk is a consequence of a portion of the blood from the portal vein passing into the systemic venous system through anastomosing branches. The

[1] Clinical Treatise on Diseases of the Liver. Sydenham edition, vol. ii. p. 384.

[2] For clinical facts on which these and other statements are based, *vide* paper by the author entitled *Clinical Report on Hydro-Peritoneum, based on an Analysis of forty-six Cases*, American Journal of Medical Sciences, April, 1863.

superficial veins of the abdomen in some cases, of the chest in other cases, and sometimes in both situations, become more or less dilated, presenting a varicose appearance. Hernial protrusions at the umbilicus and in other situations are occasionally produced.

Œdema of the lower extremities is a pretty constant symptom, the amount of œdema varying much in different cases. The limbs, scrotum, and penis sometimes become enormously swollen. Some œdema of the lower limbs preceded the enlargement of the abdomen in one-half of the cases (21), among those analyzed by me, the histories of which contained information on this point. An examination of these cases disproved a statement which has been made with respect to the significance of œdema of the lower extremities preceding the abdominal dropsy, viz., that it denotes disease of either the heart or kidneys.[1] Œdema of the face and upper extremities does not belong to the clinical history of hydro-peritoneum. If present, it denotes coexisting renal or cardiac disease. In the progress of the affection, emaciation and pallor become marked. The attenuation of the upper part of the body, the distended abdomen and the œdematous lower extremities, combine to render the appearance highly characteristic of the affection. Cholæmia or icterus is occasionally present; it occurred in 7 of the 46 cases which I have analyzed.

Febrile movement does not attend the progress of this affection. The pulse may be more or less increased in frequency and proportionately feeble, or it is more or less enfeebled without acceleration. The urine is frequently scanty. Purpurine may be present in the urine, giving rise to an appearance of hæmaturia. The mind is usually intact, but, in a certain proportion of cases, toward the close of life, delirium, convulsions, and coma occur. These symptoms may be due to uræmia or to retention in the blood of the excrementitious principles of the bile (cholesteræmia).

The mode of dying, in the great majority of cases, is by slow asthenia. A rapid and large accumulation of liquid may destroy life by interference with respiration; and apnœa and asthenia are combined when coma precedes death.

The prognosis in most cases is extremely unfavorable. The cases in which a permanent recovery takes place are very few. The morbid conditions on which the affection is dependent are generally incurable, and lead to its return, sooner or later, in most of the cases in which the dropsy disappears or is removed. The duration of the affection is variable. In the fatal cases of those which I have analyzed, the duration varied from six weeks to seventeen months, the average duration being about five months.

The diagnosis of hydro-peritoneum is generally made without difficulty, yet there is a liability to errors which may lead to serious results. A distended bladder has been punctured, the case being supposed to be one of peritoneal dropsy. It is said that John Hunter committed this unfortunate mistake. On careful examination, the tumor formed by the distended bladder may generally be felt through the abdominal walls; but the introduction of the catheter is the diagnostic test. My colleague, Prof. Sayre, was called upon to puncture the abdomen in a case supposed to be one of dropsy. He was struck at once with the unusual appearance of the abdomen, which projected notably in front and was contracted at the sides. A little milky liquid was withdrawn by introducing the catheter and employing suction by means of an India-rubber bag. Death taking place, with the symptoms of uræmia, it was found, after death,

[1] *Vide* Report, *op. cit.*

that the case was one of sacculated bladder, the saccular appendage being situated above and measuring twenty-eight inches in circumference. Pregnancy, the liquor amnii being unusually abundant, has been mistaken for dropsy, and the uterus punctured. Careful examination through the abdominal walls and *per vaginam*, together with auscultation of the abdomen, should prevent this error. Great corpulency has led to error and the operation of paracentesis, as in the famous case of "dry tapping" related in the lectures of Sir Astley Cooper. Finally, tympanites, large abdominal tumors, and ovarian cysts are to be discriminated from peritoneal dropsy.

The enlargement of the abdomen from dropsy commences at the lower part, and, if the abdomen be not largely distended, it is more marked below than above when the patient stands or sits. The enlargement on both sides is equal; the abdomen is symmetrical. If the patient lie upon either side, the weight of the liquid causes the depending side to sag. Percussion on one side, the open palm being placed on the opposite side, frequently causes a characteristic shock, called the sense of fluctuation. Sometimes this sensation is more appreciable when the palm is placed near the point at which the percussion is made. The former method of percussion gives rise to what is called diametrical and the latter to peripheral fluctuation. But a more satisfactory application of percussion is to compare the results when the patient is placed in different positions. Percussing first in the sitting or standing posture, tympanitic resonance, from intestinal gas contained in the intestines floating upon the liquid, is usually found at the upper part of the abdomen, extending below for a greater or less distance, and flatness from this point to the pubis. Placing now the patient on the back, the change in the relative situation of the liquid and intestines is shown by the greater extension of the tympanitic resonance toward the pubis. Similar proof of the presence of liquid is obtained by percussing upon one side of the abdomen successively when the body is inclined to that and the opposite side. The exceptional cases in which this test afforded by percussion is not available are those in which the intestines are fixed by morbid adhesions. This is rare in cases of a purely dropsical affection. The several affections simulating dropsy which have been named may generally be excluded by the application of percussion as just described. Ovarian cysts of sufficient size to distend the whole abdomen are the most likely to be confounded with hydro-peritoneum. These are generally, however, distinguishable by the appreciation of the cyst through the abdominal walls, the existence of a tumor on one side before it extended to the whole of the abdomen, the absence of symmetry in the enlargement of the two sides, together with the want of evidence of the presence of liquid in the peritoneal sac afforded by percussion when the body is placed in different positions.

The treatment of hydro-peritoneum relates, *first*, to the dropsical effusion, and, *second*, to the morbid conditions on which the effusion depends. As regards the dropsical effusion, the object is to effect its removal or diminution. For this object, medicinal and surgical measures may be employed. The medicinal means consist of remedies to eliminate water from the blood, and thereby induce absorption of the effused liquid. The elimination of water from the blood is to be accomplished by diuretics and hydragogue cathartics. Diuretics, in most cases, effect but little. It is difficult generally to obtain much diuretic effect from any of the remedies of this class, the difficulty arising from the slowness with which the remedies enter the general circulation, owing to the fact that the morbid conditions giving rise to the dropsy usually involve obstruction to the

portal circulation. Of 13 cases treated with diuretic remedies, in 8 no effect upon the dropsy was produced; in 5 more or less diminution of the dropsy followed, but in only 2 cases was the improvement marked and progressive. Little dependence, therefore, is to be placed on diuretics, but inasmuch as, if properly prescribed, they do not cause much disorder or prostration, they should be fairly tried. The saline and vegetable diuretics may be given in succession, and a diuretic effect is more apt to be produced if several are employed at the same time.

Hydragogue cathartics act more efficiently than diuretics; but clinical observation does not furnish much evidence of success from their use. Of the different hydragogues, elaterium is the most reliable. I am accustomed to prescribe this remedy in doses of a quarter of a grain repeated at short intervals until abundant liquid evacuations are produced. Afterward the doses may be repeated according to circumstances. Of 17 cases in which this remedy was employed, in 9 no appreciable benefit followed; of the remaining 8 cases, in one case only was the dropsy removed, in the other cases more or less diminution taking place. In all the effect was only temporary. Owing to the disturbance and prostration caused by the prolonged use of hydragogues, they are liable to do harm, and should not enter largely into the treatment.

The *apocynum cannabinum*, or Indian hemp indigenous in this country, is considered by some an efficient hydragogue in this form of dropsy. From some trial of this remedy in Bellevue Hospital, I have been led to think it is less reliable than the elaterium. The decoction of the root may be employed, or the extract.

It is important to bear in mind that, in order to secure the desired effect of diuretics or hydragogue cathartics upon the dropsy, the ingestion of liquids is to be restricted, the patient drinking no more than the wants of the body require.

The surgical method of effecting the removal of the liquid is tapping. With respect to this operation, the views generally held are, that it is to be resorted to only when the abdominal distension occasions great distress or danger, and not until the indirect means have been thoroughly tried; that the dropsy generally increases more rapidly after the operation, and that the operation involves danger if the system be much prostrated. I have been led to think that these views are erroneous. Tapping effects promptly, without perturbation and without impairing the vital powers, the object for which diuretics and cathartics are employed, measures generally ineffectual, disturbing the digestive functions, and enfeebling the powers of life. The operation is a trivial one, involving little risk of accidents or of peritoneal inflammation. A patient came under my observation at the Long Island College Hospital, who had repeatedly tapped himself, using, as a trocar, a blade of a pair of scissors, and a piece of an ordinary clay pipe-stem as a canula. There is no danger from increased rapidity of effusion directly after the operation. The patient is spared, not only the inconvenience and distress, but the permanent injury caused by the prolonged pressure of the liquid upon the abdominal and thoracic viscera, and he is in a condition more favorable for other remedies than those which have special reference to the removal or diminution of the dropsy. Clinical experience shows that, in some cases, even when the dropsy is dependent on cirrhosis, the liquid does not accumulate for weeks or months after the operation. In a case which has come under my notice, after two tappings, there was no reaccumulation for six years. In another case which I saw in July, 1865, with my colleague Prof. J. C.

Hutchison, and with Dr. Farnham, of New York, the patient, a female somewhat advanced in life and feeble, was tapped, and, after the withdrawal of a large amount of liquid, a tumor was felt just below the epigastrium. The abdomen refilled in a short time, and tapping was again employed. Since the second tapping the dropsy has not returned, nearly a year having elapsed, although the tumor has increased in size. In this case there was no ground for suspecting cirrhosis of the liver. It seems to me judicious to resort to tapping as soon as the accumulation of liquid is sufficient to occasion much inconvenience, adopting this direct method in lieu of the indirect means, provided the latter do not prove immediately efficacious, and repeating the operation whenever the abdomen becomes again distended. These views are based on the results of tapping in 20 cases under my observation, the operation in these cases being performed but once in 11 cases, and in the remaining 9 cases being repeated from three to thirty times.[1] The conclusions drawn from the facts contained in the histories of these cases are as follows: 1. Tapping may be resorted to as a palliative measure, when the condition of the patient is such that only temporary relief is to be expected. 2. In a certain proportion of cases the dropsy returns more or less quickly, and it may be necessary to repeat the operation many times. The repetitions, however, are innocuous. This was illustrated in one case in which it was performed thirty times in 18 months. 3. In some cases the dropsy does not return for a considerable and even a long period. That it will prove a curative measure is not to be expected in the vast majority of cases.

The dropsical collection is sometimes discharged spontaneously, the walls of the abdomen becoming attenuated by distension, and rupture taking place. The perforation, in these cases, is most likely to occur at the umbilicus or at some point at the median line. In a case at Bellevue Hospital, a protrusion of a cyst-like tumor took place at the umbilicus, which, after attaining to a large size, burst, and the contents of the peritoneal sac were discharged through the opening. This patient is now under my observation, four months after the spontaneous discharge took place, and the dropsical effusion has not yet returned.

The treatment relating to the morbid conditions on which the dropsy depends embraces, in the first place, measures to prevent an increase of the incurable lesion which exists in the great majority of cases, viz.; cirrhosis of the liver. It will be seen, when we come to consider this lesion, that it is generally caused by spirit-drinking. Change of habits, as regards the use of spirits, is, therefore, the most important of the measures coming under this head. In the second place, certain accessory or co-operating causative conditions may be removed, causes which act by impoverishing the blood and impairing the forces which carry on the circulation. This part of the treatment embraces tonic medication with nutritious diet, and other measures to strengthen and invigorate the system. Well-directed treatment for this end, although rarely curative, will often do much to prolong life, and to secure as much improvement of health as is compatible with existing structural lesions.

Scarification of the genital organs, when these become greatly œdematous, is apt to lead to gangrene and sloughing. This has occurred in three cases under my observation.

[1] For details of these cases, *vide* Clinical Report, *op. cit.*, from which the remarks on tapping are borrowed. During the period from the publication of the first to the fourth edition of this work (six years), I have observed many cases which exemplify the correctness of the practical views presented in the text.

Mechanical compression of the abdomen, after tapping, by means of a swathe or a laced supporter, is a measure of importance, as not only affording comfort, but tending to prevent a renewal of the dropsical effusion.

CHAPTER XI.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN.

Acute Diffuse Hepatitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Circumscribed Suppurative Hepatitis. Suppurative Portal Phlebitis. Cirrhosis of the Liver.

OF the affections of the solid abdominal viscera, the greater number by far, and the more important, are seated in the liver. These will be considered, and afterward the affections of the spleen and pancreas. I shall first consider the hepatic diseases which are undoubtedly inflammatory; next structural lesions of the liver; and, lastly, functional affections of this organ. Acute inflammation of the liver, or hepatitis, is presented in two forms, viz., *diffuse hepatitis*, that is, the inflammation extending over the whole or greater part of the organ, and *circumscribed*, *suppurative hepatitis* or *hepatic abscess*. These two forms claim separate consideration. Suppurative inflammation of the portal vein, *portal phlebitis*, will be considered in this connection. *Subacute* or *chronic hepatitis* is generally supposed to be the essential pathological condition leading to the structural lesion known as *cirrhosis of the liver*. Aside from the latter, we have no precise clinical knowledge of subacute or chronic hepatitis. Congestion of the liver, which some authors recognize as a distinct affection, will be noticed among the functional affections of this organ (*vide* chapter xiii.) and, also, as an incidental element in treating of different affections. The first disease to be considered is acute diffuse hepatitis, called by some authors parenchymatous hepatitis. In view of the extreme infrequency of this disease, save in tropical climates, and the deficiency of exact information respecting it, in the present state of knowledge, a brief space only will be devoted to its consideration.

Acute Diffuse Hepatitis.

Of the rare affections, in the cold and temperate zones, this is one of the rarest. It is said to be not infrequent in tropical climates, but in the latter, inflammation of the liver is oftener circumscribed than diffuse. The inflammation in this affection is seated in the perenchyma of the liver. Inflammation of the portion of serous membrane which invests the liver, called *peri-hepatitis*, has been noticed under the head of partial peritonitis.

Anatomical Character.—Pathologists are not agreed respecting the morbid changes, apparent after death, which denote this disease. Mere hyperæmia or congestion is not adequate evidence that inflammation has existed. The same statement is to be made concerning simple softening

of the hepatic parenchyma. Both, doubtless, are effects of inflammation, but both may be non-inflammatory. A fibrinous exudation is an effect of inflammation here as in other parenchymatous structures. This exudation takes place at the peripheral portions of the hepatic lobules. The organ is also infiltrated with a sero-albuminous liquid which escapes freely from cut surfaces. The presence of exudation and serous infiltration occasions, at first, more or less enlargement of the organ, but the atrophy induced by the pressure of the morbid deposit may lead to subsequent diminution of volume. The peritoneal covering participates in the inflammation, like the pleura in pneumonitis, and the surface becomes opaque and roughened. The parenchyma is more friable than in its healthy condition. Microscopical examination shows destruction of the liver cells. Subsequently, pus may be formed, and the structure of the organ may be more or less broken down or destroyed. The pus may be collected in abscesses varying in number and size, and in some cases the appearance of the purulent collections shows that several abscesses, at first distinct, have coalesced. The abscesses are generally lined with a pyogenic membrane, but sometimes this is wanting. The pus is generally of the kind called laudable, but is sometimes sanious and offensive. Gangrene has been observed, but is exceedingly rare. In favorable cases, the exudation and effused serum are absorbed without leading to the formation of pus and destruction of the parenchymatous structure. Death may take place, on the other hand, before the latter results take place. In a fatal case, which has fallen under my observation, the gross characters consisted of a considerable increase of the size of the organ from exudation and effusion, the enlargement having taken place, as shown by physical examinations, after the date of the attack. In this case there was no breaking down of the tissues nor production of pus, the life of the patient not being sufficiently prolonged for these effects. In another case the liver was much enlarged, weighing eight pounds, and in portions, which were estimated to be about three-fifths of the organ, the structure was broken down and mixed with bloody serum and purulent matter. The peritoneal covering was coated with lymph.

The changes belonging to the condition called *acute* or *yellow atrophy of the liver* are attributed by Bright, Frerichs, and others, to acute diffuse inflammation. The correctness of this view, however, is questionable. This condition will be noticed in connection with the structural affections of the liver.

Clinical History.—In describing this disease, writers have not been careful to distinguish diffuse from circumscribed inflammation; moreover, the existence of the disease has frequently been based on morbid appearances after death which are of a doubtful character. Hence, it is difficult to determine its symptomatology with as much precision as is desirable; its clinical history is not, as yet, satisfactorily established.

The disease may be ushered in by a chill more or less marked, and a succession of chills sometimes occurs. Febrile movement follows. Pain in the region of the liver is usually felt, but not invariably. The pain is sometimes dull or obtuse, and sometimes sharp or lancinating. If the latter character be marked, it is fair to infer that the peritoneal covering is implicated. Shooting of the pain into the right shoulder was formerly considered a pretty constant symptom, but later observations appear to show that this is the exception rather than the rule. More or less tenderness on pressure exists over the site of the liver. As regards the degree of pain and tenderness, there is much variation in different cases.

A sense of tension and weight is frequently felt in the right hypochondrium. Icterus, or jaundice, occurs in the majority of cases, but is not a constant symptom. The appetite is lost; thirst is usually marked; nausea and vomiting take place in a certain proportion of cases. Looseness of the bowels occurs in some cases, in other cases the bowels are constipated, and the two conditions may alternate. Respiration is not embarrassed, as a rule, provided the hepatitis be not associated with some pulmonary complication. Considerable importance has been attached to a decubitus on the right side, with the head raised, together with a disinclination to change the position of the body, and especially to lie on the left side. These points relating to decubitus, however, are not observed in all cases. The urine, if icterus be present, contains bile. Albuminuria is a frequent symptom. The pulse at first may be quite frequent, and afterward its frequency may diminish, and irregularity be marked. Cephalalgia is generally a symptom having more or less prominence. Somnolency and delirium are apt to precede a fatal termination, but, in some cases, the mental faculties remain intact to the close of life.

Pathological Character.—The character of this disease is essentially the same as that of acute inflammation affecting other glandular organs, for example, the kidneys; and, according to Frerichs, the disease is accompanied frequently with inflammation of the kidneys. To compare it with a disease less rare than acute nephritis, the local events are analogous to those in pneumonitis. Engorgement and exudation are the primary events, as in inflammation of the pulmonary parenchyma; if resolution take place, the exudation is absorbed, and the hepatic structure remains intact, but, if the disease do not pursue this favorable course, either purulent infiltration or the formation of abscesses ensues, involving more or less destruction of tissue, as in the third stage of pneumonitis. It is probable that the point of departure for the inflammation in this variety of hepatitis is in the hepatic cells.

Causation.—Acute hepatitis is almost peculiar to tropical climates. Its causation, therefore, is in some way connected with climate; but the rationale of the climatic influence is not understood. Of the two cases noticed under the heading Anatomical Characters, in the last the patient was attacked on shipboard in a vessel from a tropical climate. The disease rarely occurs under the age of 20. Various causes have been assigned by different writers, such as the abuse of alcoholic stimulants, the excessive use of purgatives, depressing emotions or great mental excitement. The supposed agency of these and other causes is by no means established. Hepatitis is apt to accompany or follow dysentery in tropical climates, but the inflammation, under these circumstances, is generally circumscribed, not diffuse. In the case just referred to, in which the patient was from a tropical climate, the disease was associated with dysentery. Acute diffuse hepatitis may be associated with other affections, such as pneumonitis, pleuritis, intermittent fever, etc. Contrary to the doctrine formerly held, viz., that the inflammation is generally propagated from the gastro-duodenal mucous membrane to the liver, this membrane is rarely inflamed in conjunction with acute hepatitis. The etiology of the disease requires further elucidation.

Diagnosis.—The diagnosis is sufficiently easy, provided all or most of the diagnostic symptoms be present. Pain in the right hypochondrium, and tenderness, with febrile movement, chills, anorexia, and the occurrence

of jaundice, render the existence of the disease highly probable; and if, in addition to these symptoms, the liver be found to undergo an enlargement not attributable to congestion from disease of the heart, the diagnosis is quite positive. Enlargement of the liver is an important point in the diagnosis, if it be certain that it has occurred after the date of the attack. But the enlargement may not, in all cases, be sufficient to be appreciated by physical examination, and at a late period of the disease the organ may become diminished in volume. Pain, tenderness, and icterus are not always present. Icterus, in the great majority of cases, occurs independently of hepatitis, and is, therefore, in itself no evidence of the existence of the latter disease. If the three symptoms just mentioned be wanting, the disease is latent and may readily be overlooked. Pain and tenderness in the region of the liver may be due to other affections, viz., pleuritis, pneumonitis, intercostal neuralgia, and muscular rheumatism. The two former of these affections were formerly, doubtless, not infrequently confounded with hepatitis; but, with our present knowledge of physical signs, they are readily excluded. It is, however, to be borne in mind that they may coexist with hepatitis. Intercostal neuralgia has its diagnostic criterion, which has been considered, and this affection, therefore, is easily excluded. Muscular rheumatism is not likely to be limited to the site of the liver; careful examination will suffice to show that the pain and tenderness are in the walls of the abdomen, and this, with the absence of icterus and enlargement of the liver, renders the discrimination not difficult. A friction murmur, caused by the rubbing together of the peritoneal surfaces, when these are covered with lymph, is sometimes observed over the site of the liver. This physical sign was well marked in one of the cases under my observation, to which reference has been made.

In our climate, the great infrequency of acute hepatitis is to be taken into account in the diagnosis. In view of its infrequency, evidence of the existence of the disease, which, in a tropical climate, should be deemed sufficient, may seem insufficient for a positive diagnosis. Hence, in a tropical climate, the liability to error in diagnosis is perhaps in deciding that the disease exists on insufficient grounds; whereas, in a cold or temperate climate, the error most likely to occur is failure to recognize it when present.

Prognosis.—Acute diffuse hepatitis is a disease attended with much danger. Data for determining the death-rate in this disease are wanting; but a fatal termination is undoubtedly the rule if the disease proceed to the stage of suppuration. The fatality is increased by the frequent association of other diseases. The course of the disease is usually rapid. Its duration generally is not beyond three weeks. Life, however, in some cases, is prolonged for a much longer period; and if recovery take place after the formation of abscesses, the convalescence is apt to be tedious. If abscesses form, and life be sufficiently prolonged, the pus is liable to be discharged in different directions, viz., through the abdominal or chest-walls, into the colon, stomach, peritoneal cavity, etc. As regards the prospect of recovery, much will depend on the direction in which the pus is discharged. This topic will be considered under the head of circumscribed hepatitis or hepatic abscess.

Treatment.—This disease is to be treated on the general principles applicable to the treatment of other inflammations. Bloodletting, local

or general, is to be employed, or not, according to the circumstances which either indicate or contra-indicate this remedy in inflammatory affections generally. Revulsive applications over the affected organ, such as sinapisms, dry cups, and stimulating liniments, are, to a certain extent, useful; but counter-irritation by means of blisters, or other severe applications, is of doubtful propriety. Opium is indicated in proportion to the amount of pain and constitutional irritation. Mercury has been supposed to be specially adapted to the treatment of all hepatic diseases. There are no reasons, however, for its application to this more than to other acute inflammations. Whatever usefulness it may have, here as in other inflammatory affections, consists in a so-called antiplastic and a sorbefacient influence. In so far as it may tend to increase the secretory action of the liver, its action is probably unfavorable; but the doctrine so long held, that mercury increases the secretion of bile, is, to say the least, open to much distrust. Of doubtful propriety in all cases if carried to the extent of inducing mercurialization, it cannot fail to be injurious in patients anæmic or with enfeebled, broken-down constitutions. Inasmuch as the danger lies especially in suppuration, tonic remedies and a nutritious diet are indicated early in the disease; and, when suppuration has taken place, the reliance must be on the constitution of the patient, aided by efficient supporting measures.

Circumscribed Suppurative Hepatitis, or Abscess of the Liver.

In this variety of hepatitis the inflammation is limited either to a circumscribed portion of the parenchyma of the liver or to several distinct portions. Clinically, the existence of this variety of the disease is generally not known until suppuration has taken place, and an abscess is ascertained, either by manual exploration or by the escape of the pus from some outlet into which it is discharged. Practically, therefore, it suffices to consider circumscribed hepatitis under the head of hepatic abscess. The formation of pus within the liver, in the cases in which the veins of the liver have been supposed to be the seat of inflammation, differs, in certain respects, from suppuration in cases of ordinary circumscribed hepatitis, and will be considered under the head of *portal phlebitis*.

In the majority of cases a single abscess only is formed, but in some cases there are two or three, and rarely more than three. The size of the abscess varies much in different cases. It is usually of considerable, and not infrequently of large size. In a case under my observation, five and a half quarts were at once evacuated by an opening made through the thoracic walls. After a profuse purulent discharge for several months, this patient recovered, resumed the occupation of a hack-driver, and two years afterward was in robust health. A case came under the observation of Dr. J. R. Lothrop, at Rainsford Island Hospital, in which an abscess was found to contain, after death, eighteen pints of pus, the entire organ, except the left lobe, being transformed into a mere sac. The abscess may be situated at any part of the gland. It is much oftener seated in the right than in the left lobe, and oftenest at the posterior portion of the right lobe. It may be superficially or deeply seated. The purulent matter from an hepatic abscess may not differ in its characters from ordinary pus, but frequently it contains more or less of the detritus of the hepatic tissue, and it sometimes contains bile. The walls of the abscess at first consist of the exposed hepatic tissue, but, after a time, a cyst is formed which increases in thick-

ness and firmness with age. The walls of the abscess occasionally become gangrenous.

It is doubtful whether a considerable collection of pus within the liver be ever completely absorbed. It may remain in an indolent, latent condition for an indefinite period, but, sooner or later, if life continue, the pus makes its way, as in other abscesses, in the direction in which the pressure is least, and is at length discharged into some cavity, canal, or outlet.

In the larger proportion of cases, the evacuation is through the thoracic or abdominal parietes. When it takes this direction, a fluctuating tumor, after a time, makes its appearance upon the surface, caused by the accumulation of the pus beneath the integument. The tumor, if left to itself, increases, becomes pointed, the skin becomes reddened, and finally the discharge is effected by ulceration. The most frequent situation of the tumor is below the ensiform cartilage, but it may appear at any point over the site of the liver. Sometimes the pus burrows beneath the integument, and the tumor is situated at a greater or less distance from the liver. It has been observed as high as the axilla, and below on the inner side of the thigh; in the latter case it is liable to be mistaken for lumbar abscess. Of course, partial peritonitis and adhesion over the circumscribed space occupied by the abscess are essential in order that the pus may be discharged externally. This conservative provision does not always precede the opening of the abscess, and then the contents are discharged into the peritoneal cavity; peritonitis is at once developed, and, under these circumstances, death speedily follows. The direction, next in frequency, which the pus takes is through the diaphragm into the chest. Partial peritonitis precedes the perforation of the diaphragm, and partial pleuritis ensues, frequently limited to a small space, preventing evacuation into the pleural cavity. Occasionally, however, the latter conservative provision does not take place, and the pus, discharged into the pleural cavity, at once causes general pleuritis. If this be prevented by adhesion around the opening through the diaphragm, the lung becomes perforated, and the evacuation is into the bronchial tubes, the pus being discharged by expectoration. The abscess is sometimes evacuated into the pleural cavity, and afterward perforation of the lung takes place, and the pus is expectorated. Other less frequent directions in which the pus is discharged are the following: Into the colon, stomach, or duodenum, the pus being then discharged by vomiting or stool; into the pericardium, followed, of course, by instant death; into the pelvis of the right kidney, the pus discharged with the urine; into a hepatic vein, or the vena cava, giving rise to purulent infection of the blood; into the gall-bladder or biliary ducts, and thus, if there be no obstruction, the pus finding its way into the duodenum.[1] In a case which came under my observation at Bellevue Hospital, an abscess pointed externally and was opened; subsequently perforation of the stomach took place, and liquids ingested escaped through the external opening, the patient dying from inanition.

The clinical history of hepatic abscess is obscure. The symptoms rarely point distinctly to this affection. Pain exists if the hepatitis be near the surface of the liver, and whenever partial peritonitis ensues, but, even then, pain is not always a prominent symptom, and, if the inflammation be deep-seated, there may be no pain. Pain is felt in the right shoulder

[1] For statistics showing the relative frequency of the evacuation of hepatic abscesses in these different directions, and other details, the reader is referred to *A Clinical Treatise on Diseases of the Liver*, by Dr. Fried. Theod. Frerichs. Published by the New Sydenham Society, London, 1861.

in a small number of cases. Rigidity of the abdominal walls over the liver, or of the right rectus muscle, is a sign to which much importance is attached by several observers. Febrile movement is rarely marked, and may be wanting. Chills usually occur during the suppurative process. These sometimes occur regularly, simulating intermittent fever, but generally they are irregular. Jaundice is rare. The appetite and digestion may be more or less disturbed, or they may be unaffected. The nutrition may be but little, or not at all, affected. Reference is now had to symptoms prior to the discharge of the pus or its appearance beneath the integument. The affection is not infrequently completely latent. It is not uncommon, in tropical climates, to find an abscess in the liver in bodies dead with various diseases, when hepatic disease had not been suspected during life; and the first intimation of the existence of this affection during life, in certain cases, may be the discharge of pus from the stomach, bowels, or air-passages.
